If one suspects Lynch syndrome on the basis of multiple first-degree relative involvement or early age of tumor onset, colonoscopy is the most appropriate screening approach, and it should be undertaken at least every other year. Screening intervals of 3 years or more, which are appropriate for sporadic colorectal cancer, are not appropriate for Lynch syndrome, as interval cancers can occur (156,193). In patients whose histories do not suggest Lynch syndrome, less rigorous screening programs are appropriate, but should be tailored to the degree of estimated risk. In the general population, colonoscopy is the optimal diagnostic modality for screening, and a negative colonoscopic examination can usually assure a relatively low likelihood for the development of a lethal malignancy within the subsequent 3–5 years (194). Moreover, when there is a history of a single first-degree relative with colorectal adenoma or cancer at an older age (i.e. >60 years), there may be no important increase in risk for colorectal cancer compared to the general population (192), and a targeted, intense screening program is unnecessary. Nonetheless, the risk of colorectal cancer in North America and western Europe is sufficiently high that annual fecal occult blood testing and periodic flexible sigmoidoscopy have been recommended for the general population, and an estimation of increased risk affects the age at which screening begins, the use of colonoscopy (rather than only sigmoidoscopy), and the use of periodic surveillance examinations. Several studies have demonstrated that colonoscopy is relatively less effective in preventing proximal vs distal colorectal cancers, for a variety of reasons (195,196). Therefore, particular care must be exercised by the colonoscopist to carefully examine the proximal colon in Lynch syndrome patients, to avoid the unfortunate occurrence of “interval cancers” (156).

When syndromic colon cancer is strongly suspected, a more aggressive approach is indicated. If FAP is suspected in a family, the optimal approach is to find the germline mutation in a family member who is definitely affected with the disease. Then, first-degree, at-risk relatives should be offered testing accordingly. If a mutation

is found in an affected family member, this information can be very helpful in making the diagnosis of FAP or excluding it definitively. It is essential to definitively identify the mutation in an affected individual in a family, since not all mutations are detectable with the current diagnostic strategies; thus, obtaining a negative genetic test in the relatives of an affected individual in whom the germline mutation has not been found is not definitive. Once identified, one can test siblings and offspring, and if the test is negative for a known mutation, the patient can be reassured, and no more endoscopic surveillance is necessary.

#### 70.3.2.12 Other Possible Forms of Non-Lynch Syndrome, Nonpolyposis Familial Colorectal Cancer.

There are still forms of familial colorectal cancer for which the germline mutations are not known. Familial clusters of colorectal cancer with variable types of MSI (MSI-V) have been identified, but the genetic basis of this has not been found. These families always meet the Bethesda criteria, often meet the Amsterdam criteria (55% of families), frequently have *BRAF* mutations (V599E), frequently have methylation of the promoter of the *MINT31* gene, and may progress through a unique carcinogenetic pathway (197).

There is a slight increase in colorectal cancer among individuals with a germline sequence variation in the transforming growth factor type 1 receptor. This sequence variation, called *TGF $\beta$ R1*\*6A, does not produce a phenotype of highly penetrant familial cancer by itself (198). However, this could be a modifier gene that interacts with other factors, either environmental or genetic, to increase the risk of cancer.

### 70.3.3 Genome-Wide Association Studies of GI Cancers

Several large collaborations have attempted to find additional genes for familial GI cancer using genome-wide association studies (GWAS), in which a large number of SNPs are tested for linkage to a specific phenotype (such as colorectal cancer) in a large number of patients. One locus at 8q24.21 has been found repeatedly by several groups (199,200). Although there are very high levels of significance attributed to this locus (up to  $P = 10^{-14}$ ), the odds ratios (ORs) for colorectal cancer are relatively modest (OR = 1.27 and ~1.14 for the two studies). What is perhaps most interesting about this locus is that there is no gene or obvious functional genetic unit at or near the locus. Other collaborations and meta-analyses have confirmed the association (201–203), so the linkage is clearly real, but the mechanism by which this locus modifies risk is still an open question. One group has suggested a long-range interaction with the *MYC* locus (204), but the biology of how this modifies risk remains to be discovered.

Similarly, additional SNPs have been linked to colorectal cancer risk, including 9p24 (200,201), 8q23.3 (203,205), 10p14 (205), and 11q23 (202), typically with

similar findings: a relatively low increment of risk (all with RRs less than 2.0, most often about 1.2, and some with incremental risks <10%), and most are not located within or even near a gene. There are some exceptions, such as the identification of a SNP associated with the *SMAD7* gene (206), but generally, the hunt for common low-risk genetic variants has pointed to areas of the genome that are not populated by genes. The accumulation of multiple risk SNPs is modestly additive, but the total risk is not yet sufficient to be clinically useful as a predictive tool (discussed in (207) and (208)). Two SNPs (at 8q23.3 and 11q23.1) modify colorectal cancer risk in patients with Lynch syndrome (148), and this may be a direction in which this information can be applied clinically in the future.

## 70.4 OTHER FAMILIAL GASTROINTESTINAL POLYPOSIS SYNDROMES

The gastrointestinal polyposis syndromes are listed in Table 70-6.

### 70.4.1 Peutz–Jeghers Syndrome

Peutz–Jeghers syndrome is an autosomal dominant inherited disorder characterized by distinctive intestinal hamartomatous polyps in association with mucocutaneous melanocytic macules. The syndrome was named after Peutz, who first noted a relationship between the intestinal polyps and the mucocutaneous macules in

1921, and Jeghers' definitive descriptions in 1944 and 1949. Peutz–Jeghers syndrome occurs with a frequency between 1 in 70,000 and 1 in 200,000 people, making it one-tenth as common as FAP based on registry data. The syndrome has a male to female ratio of 1:1, and the average age at the time of diagnosis is 23 years in men and 26 years in women.

**70.4.1.1 Mechanistic Basis of Peutz–Jeghers Syndrome.** Peutz–Jeghers syndrome is inherited as a pleiotropic autosomal dominant condition with variable and incomplete penetrance (209). The germline mutation responsible for this disease is in a serine-threonine kinase on chromosome 19p13.1 referred to as *LKB1* (210–212) or *STK11* (213). Normal expression of *STK11/LKB1*, a protein containing 436 amino acids, occurs in a wide variety of adult and fetal tissues and tumors, but has predominance in epithelial cells and seminiferous tubules of the testis (214). LOH at this locus has been found in 70% of tumors of Peutz–Jeghers patients who have an *STK11/LKB1* germline mutation (215,216). In some breast carcinomas and hamartomatous polyps from Peutz–Jeghers patients, hypermethylation of the promoter of *STK11/LKB1* occurs (217).

Introduction of *STK11/LKB1* into cell lines with severely reduced mRNA levels and impaired *STK11/LKB1* kinase activity suppresses cell growth by causing a G1 cell cycle block (218). The mechanism of the cell cycle block may be due, in part, to the association of *STK11/LKB1* with p53 and regulation of p53-dependent apoptosis pathways (219). In addition, the *STK11/LKB1* protein associates with and regulates the brahma-related gene 1,

**TABLE 70-6 Intestinal Polyposis Syndromes**

Adenomatous Syndrome	Chromosomal Location(s)	Mutated Gene(s)	Inheritance Pattern
Familial adenomatous polyposis	5q21	<i>APC</i>	Autosomal dominant
Gardner's variant			
Turcot's variant			
MUTYH-associated polyposis	1p32-34	<i>MUTYH</i>	Autosomal recessive
Lynch syndrome	2p16, 3p21, 7p22, 2p16	<i>hMSH2, hMLH1, hPMS2, hMSH6</i>	Autosomal dominant

	15q21	? <i>THBS1</i>	?
	10q23	? <i>BMPR1A/ALK3</i>	?
Hyperplastic polyposis syndrome	?1p	?	?

*Brg1*, which is an essential component of the chromatin remodeling complex (220). Mutations in *STK11/LKB1* compromise its ability to stimulate AMP-activated protein kinase, resulting in impaired downstream signaling inhibition of the mammalian-target of rapamycin complex 1 (mTORC1) (221,222), a common protein shared with TSC2 signaling and mutated in the benign tumor syndrome, tuberous sclerosis complex (223). Polyps from *lkb1*<sup>+/-</sup> mice show dramatic growth suppression with rapamycin, coincident with countering the parallel upregulation of *HIF-1α* and its downstream transcriptional targets (224). Furthermore, *STK11/LKB1* itself appears to be regulated by phosphorylation through pathways that include protein kinase A and EGF/RAF/ERK (225,226).

Knockout of the *stk11/lkb1* gene in mice resulted in embryonic death in midgestation, with embryos that had neural tube defects, mesenchymal cell death, and vascular abnormalities. In extraembryonic tissues such as the placenta, *VEGF* mRNA expression was downregulated. However, overall *VEGF* mRNA was markedly upregulated in the embryos (227). These findings established a link between *stk11/lkb1* and the *VEGF* signaling pathway, and the vascular defects seen in the embryos are at least in part mediated by *VEGF*. *VEGF* is known to be regulated by *mTOR* (228).

**70.4.1.2 Clinical Features of Peutz–Jeghers Syndrome.** In childhood and early adult life, the principal causes of morbidity in Peutz–Jeghers syndrome stem from the intestinal location of the polyps (small intestine >> colon > stomach). These include small intestinal obstruction and intussusception, abdominal pain, hematochezia, and rectal prolapse, which typically occur in the second and third decades of life. Pathologically, the Peutz–Jeghers polyps are unique hamartomas with an arborizing network of smooth muscle tissue covered with non-neoplastic-appearing epithelium. The smooth muscle bands extend throughout the head of the polyp and are sufficiently characteristic pathologically to establish the diagnosis. Benign glands within the polyp may be surrounded by the arborizing smooth muscle, and may extend into the submucosa or muscularis propria. The glandular epithelium is often described as “pseudoinvasive” into the deeper layers of the polyp. The polyps are almost always multiple, and there are characteristic extraintestinal manifestations that make this syndrome easily identifiable. Early in infancy, hypermelanotic macules (1–5 mm) may be found around the mouth (often crossing the vermilion border of the lips), nose, lips, buccal mucosa, hands and feet, and may also be present in the perianal and genital regions. The lesions are flat, may be brown or greenish black and, with the exception of the buccal pigmentation, may fade at puberty. It is important to distinguish these melanin deposits from ordinary freckles, which are sparse near the nostrils and mouth and usually absent at birth.

**70.4.1.3 Cancer in Peutz–Jeghers Syndrome.** As the Peutz–Jeghers patient ages, the morbidity risk shifts to

that of malignancy, particularly cancers of the luminal GI tract, pancreas, female reproductive tract, lung and breast. There is a 15-fold elevated RR of developing cancer over the general population, and 93% of Peutz–Jeghers patients develop cancer by age 64 (229). Thus, patients may present with symptoms of cancer if the diagnosis was not previously made. GI cancers have been reported that appear to have developed from foci of adenomatous epithelium within the Peutz–Jeghers polyps. This may be due to the mutant *STK11/LKB1* in epithelial cells, which cannot activate GSK3β, preventing phosphorylation of β-catenin (230,231). In addition, acquired mutations in *CTNNB1* (but not *APC*) and *p53* are thought to be involved in progression to cancer, when this occurs (216).

The Johns Hopkins Polyposis Registry has reported the strongest evidence for an increased risk of cancer in the Peutz–Jeghers syndrome (229), and the same is true for *STK11/LKB1* mutation carriers (232). The major sites in order of RR over the general population are small intestine (RR 520), stomach (RR 213), pancreas (RR 132), colon (RR 84), esophagus (RR 57), ovary (RR 27), lung (RR 17), uterus (RR 16), and breast (RR 15.2). In addition, other reproductive site cancers have been associated with Peutz–Jeghers syndrome, including adenoma malignum of the cervix, Sertoli cell tumors, and sex cord tumors with annular tubules. With the last condition, menstrual irregularities in females (due to hyperestrogenism from sex cord tumors with annular tubules), or gynecomastia and growth acceleration (due to a Sertoli cell tumor) may be the presentation in an undiagnosed patient. Biliary adenocarcinoma risk is also elevated in patients with mutations in the *STK11/LKB1* gene (233).

## 70.4.2 Juvenile Polyposis Syndrome (JPS)

Juvenile polyps are distinctive pathological lesions that occur as solitary rectal polyps in 1–2% of children. They have a smooth surface covered by normal colonic epithelium, and the lamina propria is edematous and contains inflammatory cells. JPS is a rare autosomal dominant entity consisting of multiple juvenile polyps. Traditionally, the presence of more than 10 juvenile polyps indicates JPS, but more than five should raise suspicion. The polyps will almost always recur after endoscopic removal. JPS patients usually present by age 30, with the mean age of presentation being 9.5 years. In some families only the colon is involved, but there are families with generalized GI juvenile polyposis (234). This syndrome is diagnosed by the pathological appearance of the polyps and exclusion of extraintestinal lesions seen with the other hamartomatous syndromes (235). An estimate for prevalence in the population is 1 in 250,000 individuals. JPS patients often present with rectal bleeding, but with a large number of polyps, patients can present with GI protein loss, malnutrition, cachexia, and failure to thrive, typically in the first decade of life. Large polyps can cause obstruction or altered bowel habits. The average age for

colorectal cancer presentation is 34 years, so anemia and obstruction from tumor can be presenting symptoms later in life.

**70.4.2.1 The Genetic Basis of JPS.** The genetic basis for JPS centers on bone morphogenic protein (BMP) signaling. Initially, some patients with JPS features showed deletions of chromosome 10q23 (236–238) and mutations in *PTEN*, the affected gene identified for Cowden syndrome and Bannayan–Riley–Ruvalcaba syndrome (BRRS). However, the deletions on chromosome 10q23 also encompassed or surrounded the locus for the type 1 receptor for BMP, *BMPR1A*. Moreover, young patients who, because of their age, could not be classified phenotypically into any hamartomatous polyp syndrome other than JPS, later developed the extraintestinal manifestations of Cowden disease, removing *PTEN* mutations as a cause for true JPS (239–241). No *PTEN* mutations were detected in 14 families and 11 sporadic cases of JPS (242).

Linkage analysis in families without *PTEN* mutations revealed that the aforementioned gene on chromosome 10q23, *BMPR1A*, is mutated in the germline of some JPS families (243). The mutations result in premature truncation of this cellular transmembrane protein that mediates BMP signaling. Several BMP ligands bind to specific type II BMP receptors, which then activate *BMPR1A* through a glycine-serine rich domain. Subsequently, *BMPR1A* phosphorylates SMAD1, SMAD5, and SMAD8, which then associate with SMAD4 to form heteromeric complexes that translocate from the cytoplasm to the nucleus, and associate with DNA-binding proteins to regulate transcription of genes that control apoptosis and mesoderm formation. The demonstration of germline mutations of *BMPR1A* in JPS patients was the first evidence that BMPs play a role in controlling colonic epithelial growth and neoplasia. BMP signaling can regulate *PTEN* via a non-SMAD pathway, suggesting interconnectivity among the hamartomatous polyposis syndromes (244).

A separate large kindred with JPS demonstrated linkage to chromosome 18q21.1 (245). Subsequently, three familial and two sporadic JPS cases demonstrated germline mutations in the *SMAD4* gene at chromosome 18q21.1, whose gene product encodes a key intracellular signal transducer and transcriptional regulator for the TGF $\beta$  superfamily of ligands and receptors, which includes BMP (246). The most common *SMAD4* mutation was a 4-bp deletion from codons 414–416; however, a 2-bp deletion from codon 348 and a 1-bp insertion at codon 229 have also been reported. All these mutations are predicted to cause a truncated SMAD4 protein that would prevent the requisite homotrimerization at its carboxyl terminus. The prevalence of *SMAD4* and *BMPR1A* mutations in JPS appears to be 18.2 and 20.8%, respectively, suggesting that additional genes or alternative means of inactivating the known genes are involved in this syndrome (247).

In addition, germline mutations of *SMAD4* can phenotypically cause hereditary hemorrhagic telangiectasia

(HHT), and thus careful examination for findings associated with both syndromes should be undertaken in these patients (248,249) (see Chapter 49). Mutations in another gene, *ENG*, encoding endoglin, a chaperone protein for TGF $\beta$  superfamily signaling, had been found to be a cause of HHT, and were also identified in the germline of some JPS patients (241,250). The overlap between JPS and HHT was borne out because of insights brought by genetics, and led to the discovery of a key phenotypic feature that had not been appreciated previously.

Germline mutations can be identified in only about ~40% of JPS patients. Large deletions that encompass *SMAD4* and *BMPR1A* are often missed by routine DNA sequence analysis, but when sought, may raise the identification of germline mutations to ~60% of patients (251,252). These large deletions are often seen in JPS with other associated congenital abnormalities, which can occur in up to 20% of JPS patients.

Patients with JPS are predisposed to juvenile hamartomatous polyps and GI cancer, with a 15% incidence of colorectal carcinoma in young patients and a cumulative risk of 68% by 60 years of life (234,253). BMP and its downstream signaler SMAD4 appear to suppress Wnt signaling, involved as a “gatekeeper” for colonic neoplasia (254). Juvenile polyps commonly have nuclear localization of  $\beta$ -catenin (255). Thus, dysregulated BMP signaling may predispose juvenile polyps to adenomatous evolution and later malignant transformation through this mechanism. Other tumors associated with JPS include pancreatic, gastric, and duodenal cancers (256).

### 70.4.3 PTEN Hamartoma Tumor Syndrome

Many researchers now consider BRRS and Cowden syndrome to be a single entity, with a phenotypic spectrum caused by mutations in the *PTEN* tumor suppressor gene (257). BRRS, also previously known as Bannayan–Zonana or Ruvalcaba–Myhre–Smith syndrome, was described as a rare autosomal dominant disease that consisted phenotypically of multiple hamartomatous polyps of the intestinal tract (typically juvenile polyposis), macrocephaly, lipomas and hemangiomas, cognitive and developmental delays, lipid storage myopathy, Hashimoto thyroiditis, and speckled macules of the penis or genital area (237). Cowden syndrome, also known as multiple hamartoma syndrome, was described in 1963 in which multiple hamartomas develop in the skin and mucous membranes, as well as throughout the GI tract. The hallmark of Cowden syndrome is multiple facial trichilemmomas (hamartomas of the hair follicle). All the features of Cowden syndrome and BRRS are now considered part of the PTEN hamartoma tumor syndrome. The true incidence of PTEN hamartoma tumor syndrome is not known; estimates are that it occurs in 1 in 200,000 individuals, with males and females affected equally, but it may be underdiagnosed, and much higher. It often occurs without a prior family history.

A number of unusual phenotypic features may be present in PTEN hamartoma tumor syndrome patients. These include a high-arched palate, beaked nose, and mandibular, maxillary and soft palate hypoplasia. Café-au-lait spots may be present, and some patients develop retinal gliomas, odontitis, dental caries, adenoid facies, kyphoscoliosis, and pectus excavatum. A number of extraintestinal hamartomas can develop. These may include those of mucous membranes, such as flat or verrucous papules on the tongue, gingiva, and oral mucosa. Other soft tissue tumors can also develop, including lipomas, hemangiomas, lymphangiomas, neurofibromas, meningiomas, and uterine leiomyomas. The hamartomatous polyps in the PTEN hamartoma tumor syndrome demonstrate a broad range of histology, and the most common intestinal polyp appears to be a protuberance of cytologically normal epithelium indigenous to the region from which the polyps arose; hyperplastic polyps are also common (258). Overall, the polyposis in the PTEN hamartoma tumor syndrome should be considered a mixed polyposis. Lipomas, juvenile polyps, inflammatory polyps, ganglioneuromas, and lymphoid hyperplasia can occur. A variant of Cowden's syndrome, the Lhermitte-Duclos syndrome, shares the phenotype and genotype of Cowden's syndrome, but also features macrocephaly, ataxia, and dysplastic cerebellar gangliocytomatosis (cerebellar hamartomas). Clinically, confusion of PTEN hamartoma tumor syndrome with multiple endocrine neoplasia (MEN) type 2B may occur, because both syndromes share intestinal ganglioneuromas and thyroid disease in their phenotype. However, medullary thyroid cancer occurs in MEN2B patients, whereas follicular thyroid cancer is characteristic of PTEN hamartoma tumor syndrome. Genetically, MEN2B is associated with germline mutations in *RET*, while the PTEN hamartoma tumor syndrome is associated with mutations in *PTEN*. Another syndrome that can be confused with the PTEN hamartoma tumor syndrome is the pheochromocytoma–paraganglioma syndrome, comprising papillary thyroid carcinomas, carcinoma of the breast, and renal cell carcinomas in addition to head and neck paragangliomas, adrenal and extra-adrenal pheochromocytomas (259). These two syndromes can also be distinguished by germline testing, as the pheochromocytoma–paraganglioma syndrome is associated with germline mutations in the succinate dehydrogenase genes, subunits B, C, and D (259,260). Surveillance for the appropriate tumors based on the natural history of these syndromes can then be instituted.

**70.4.3.1 The Genetic Basis of PTEN Hamartoma Tumor Syndrome (BRRS and Cowden Syndrome).** The genetic cause for PTEN hamartoma tumor syndrome is a germline mutation in *PTEN* (261), which encodes a dual-function phosphatase (phosphoserine/phosphothreonine and phosphotyrosine residues) that can dephosphorylate the lipid phosphatidylinositol-3,4,5-triphosphate after activation by the mitogenic enzyme phosphatidylinositol 3 kinase. *PTEN* mutations are found in 81%

of Cowden syndrome kindreds (262). Nearly half the mutations identified are in exon 5 of *PTEN*, the location encoding the phosphatase core motif. The PTEN protein is a tumor suppressor that, by its dephosphorylating ability, contributes to programmed cell death, and inhibits the cell's ability to migrate and invade. About 60% of BRRS patients have germline mutations in *PTEN* (263). Indeed, the reports of BRRS and Cowden disease occurring in the same family with the same *PTEN* mutation originally suggested that the two diseases might be allelic (262). Analysis of BRRS and Cowden syndrome patients with germline mutations in *PTEN* indicate a similar mutational spectrum, and correlations between *PTEN* mutations and cancers (or breast fibroadenomas) in Cowden syndrome, BRRS, or BRRS/Cowden disease families demonstrate considerable overlap (262). The overall implication was that *PTEN*-mutation-positive Cowden syndrome and BRRS were pleiotropic presentations of a single syndrome and thus were consolidated into the PTEN hamartoma tumor syndrome. Splice variants of *PTEN* may drive some of the phenotypic variations between Cowden syndrome and BRRS (264). Both should receive equal attention with respect to cancer surveillance.

Germline mutations in *PTEN* have not been found for all BRRS or Cowden syndrome patients (265). Some patients have gross chromosome deletions or rearrangements involving the *PTEN* locus on chromosome 10, thus making the patient haploinsufficient. Other patients, despite an exhaustive search for chromosomal deletions and mutations of *PTEN*, do not demonstrate abnormalities at this locus. *KILLIN*, encoding a 20-kDa protein that mediates p53-induced apoptosis, lies in close proximity to *PTEN* on chromosome 10, but is transcribed in the opposite direction to *PTEN* (266). Germline hypermethylation upstream to *PTEN* showed no transcriptional repression of *PTEN* in patients with *PTEN*-negative Cowden syndrome, but methylation of this region transcriptionally downregulated *KILLIN* more than 250-fold compared with controls (267). Patients with *KILLIN* promoter hypermethylation had a three-fold increase in breast cancer and two-fold increase in kidney cancer over individuals with germline *PTEN* mutations. Thus, germline promoter methylation of *KILLIN* may prove to be either a susceptibility gene for PTEN hamartoma tumor syndrome or part of the spectrum of its current genotype.

**70.4.3.2 The PTEN Hamartoma Tumor Syndrome and Cancer.** Two-thirds of PTEN hamartoma tumor syndrome patients will develop a goiter, and there is a 10% incidence of thyroid cancer in this condition. More than 75% of patients will have breast lesions, including fibrocystic breast disease and fibroadenomas, and 50% will develop breast cancer. The breast cancer is often bilateral, and the median age of diagnosis is 41 years. Other cancers such as renal cell carcinoma, Merkel cell carcinoma, lymphomas, endometrial cancer and melanomas are increased in PTEN hamartoma tumor syndrome.

An analysis of 127 *PTEN* mutation carriers demonstrated an increased risk for colorectal adenocarcinoma in those with polyposis, 224-fold over the general population, and all patients in the cohort with colon cancer were younger than 50 years of age (268). Thus, *PTEN* hamartoma tumor syndrome patients should be considered at high risk for early-onset colorectal cancer.

A heterozygous *pten* knockout mouse model causes neoplasia in multiple organ systems, including multiple intestinal polyps in association with the gut lymphoid tissue (269). The demonstration of an acquired DNA MMR defect within familial hamartomatous polyp epithelium suggests a potential mechanism for transformation into adenocarcinoma (270).

#### 70.4.4 Hereditary Mixed Polyposis Syndrome (HMPS)

Hereditary mixed polyposis syndrome (HMPS) is a very rare autosomal dominant syndrome in which affected family members have atypical juvenile polyps with mixed adenoma and hyperplastic elements, hyperplastic polyps, colonic tubular, villous and serrated adenomas, and progression to colonic adenocarcinomas (271). There appear to be few or no extraintestinal manifestations. At least five HMPS families have been described in the literature (272). Although the original description of a large family with HMPS had been linked to chromosome 5q (273), a subsequent analysis has determined linkage to chromosome 15q13-q14, a region containing a susceptibility locus for colorectal adenomas and carcinomas (*CRAC1*), as well as chromosome 15q21 where the tumor suppressor gene *THBS1*, encoding thrombospondin, is located (274). It remains to be determined if the HMPS locus and either *CRAC1* or *THBS1* are one and the same (272). Another analysis found linkage to chromosome 10q23, and one family had an 11-bp deletion in *BMPR1A*, the same gene involved with JPS; subsequently two of four HMPS families were found to have mutations in *BMPR1A* (275,276). The implication of this analysis is that HMPS is genotypically related to JPS, but this needs to be verified. Based on the analysis of the five known families, it is probable that all contain a common ancestral Ashkenazi haplotype. Commonly, rectal bleeding is the presenting symptom, and screening with regular colonoscopies and polyp removal has been proposed to reduce the incidence of colorectal cancer in this setting (277).

#### 70.4.5 Hyperplastic (Serrated) Polyposis

Multiple hyperplastic (serrated) polyps (>20 polyps in the colon) rarely occur in individuals and are not usually familial (278); the majority of isolated hyperplastic polyps are located in the rectum. It is now recognized that colorectal polyps with a serrated appearance may be either hyperplastic polyps (which have no apparent neoplastic potential), or serrated adenomas (which have

a considerable neoplastic potential) (279). When at least five histologically confirmed serrated polyps occur proximal to the sigmoid colon with 2 polyps >1 cm in size, when any number of serrated polyps are proximal to the sigmoid colon in a patient with a first-degree relative with hyperplastic polyposis, or when more than 30 serrated polyps of any size are distributed throughout the colon, the diagnosis of hyperplastic (serrated) polyposis should be given. Patients with hyperplastic or serrated polyposis have an increased risk for colon cancer (280,281), with predilection for the right colon, as do their first-degree relatives (282). Hyperplastic polyposis can be associated with a family history of colorectal cancer, and with alterations at chromosome 1p (278), but the genetic cause for this syndrome has yet to be identified. A familial syndrome of giant hyperplastic polyposis has been described in a single family that also met the criteria for Lynch syndrome (283). Up to 18% of MAP patients meet the criteria for hyperplastic polyposis, and an analysis of 17 MAP patients showed that 47% had serrated polyps (282). Somatic mutations in *BRAF* occur commonly in the polyps (including hyperplastic polyps, serrated adenomas, admixed hyperplastic adenomas, tubular adenomas, and carcinomas) from patients with hyperplastic polyposis (284) with few *KRAS* mutations, and many of these polyps have hypermethylation of several loci, suggesting that these lesions evolve through the CIMP pathway (33). The DNA MMR gene *bMLH1* is one of the genes susceptible to hypermethylation, so, some of these polyps may develop MSI because of loss of MMR function. Sessile serrated adenomas may be flat and relatively unapparent visually, making them difficult to observe at routine colonoscopy, and their predilection for the right colon gives rise to the predominance of right-sided cancers observed in patients with hyperplastic polyposis.

#### 70.4.6 Noninherited Forms of Intestinal Polyposis

GI polyposis may occur in a small number of conditions that represent acquired, noninherited diseases. One of these, Cronkhite–Canada syndrome, consists of diffuse GI polyposis, loss of fingernails, alopecia, cutaneous hyperpigmentation, diarrhea, weight loss and malnutrition. This syndrome typically occurs in middle-aged or older patients, and the diagnosis is made when multiple polyps are found that most resemble inflammatory polyps (285). Colorectal cancer has been reported to occur in association with the Cronkhite–Canada syndrome, but there is no evidence to indicate whether there is an excess incidence of neoplasia in this condition. In any event, the disease is not inherited and has never been reported in familial clusters, and little is known about its pathogenesis.

Other conditions may cause multiple polyps in the GI tract in the absence of any known genetic basis. These include the inflammatory polyps or pseudopolyps that

are seen in ulcerative colitis or other types of inflammatory bowel disease, lymphoid polyposis (both benign and malignant varieties), lipomatous polyposis, and pneumatosis cystoides intestinalis. These are isolated curiosities with no known genetic basis.

## 70.5 GENETICS OF GASTRIC CANCER

Gastric carcinoma is among the three most common causes of cancer worldwide. What is most remarkable about the epidemiology of stomach cancer is the relative absence of strong evidence for important inherited factors in this disease. Gastric carcinoma seems to be principally related to environmental factors, largely infection by *Helicobacter pylori*, and increased familial risks are probably related to this or other environmental factors. One commonly finds an increase in gastric cancer in Lynch syndrome kindreds, and in the largest family reported, it was noted that a predominance of gastric cancer evolved into a predominance of colon cancers during the twentieth century (99). Therefore, the first consideration in a familial cluster of gastric cancers is to consider the possibility of Lynch syndrome, particularly if the background incidence of gastric cancer is high in that geographical region (286). Gastric cancer is quite uncommon as a complication of FAP, but may be seen in Peutz–Jeghers syndrome (287).

### 70.5.1 Hereditary Diffuse Gastric Cancer (HDGC) and the *E-Cadherin* Gene (*CDH1*)

There is a rare form of hereditary gastric cancer that can be distinguished by unique pathological features, termed hereditary diffuse gastric cancer (HDGC). Germline mutations in the *CDH1* gene predispose to early-onset, diffuse gastric cancers with a linitis plastica phenotype (288). Inactivating mutations in *CDH1*, located on 16q22.1 are of high penetrance, were originally described in a Maori kindred from New Zealand (289), but have been found in patients from Europe and North America (290,291). The tumors are characterized by signet ring cells, and

begin as clinically silent multifocal clusters of intramucosal cancer. HDGC is inherited as an autosomal dominant disease, the majority of the germline mutations result in truncation of the protein, and the mutations identified thus far are scattered throughout the 16 exons (292,293). However, only 30–50% of HDGC families have germline mutations identified, making other genetic abnormalities likely (including Lynch syndrome, as described earlier). The loss of the adhesion protein E-cadherin leads to defective intracellular adhesion, which manifests as a diffuse, spreading, isolated cellular phenotype, which impedes early diagnosis. The virulence of the linitis plastica tumors has led to the recommendation for prophylactic gastrectomy in gene carriers (294). The population prevalence is unknown, but it appears to be rare.

### 70.5.2 Genetics of Pancreatic Cancer and Familial Pancreatic Cancer

Pancreatic cancer is largely thought to be caused by environmental factors, but the etiology of this disease remains enigmatic. There have been recurring reports of familial clusters of pancreatic cancer, and there appear to be many potential genetic culprits for this phenomenon. There is an excess of pancreatic cancer in a variety of genetic diseases that predispose to other GI cancers, but pancreatic cancer is not highly penetrant in any of them. It has been projected that as many as 5% of pancreatic cancer may have a genetic basis and the number of genes that might participate in this is large (295). Thus, one must consider the possibilities of germline mutations in the familial breast cancer genes *BRCA1* and *BRCA2*, in atypical mole/melanoma families with germline mutations in *p16*, in Peutz–Jeghers syndrome families (*STK11*, *PRSS1*), in Lynch syndrome (both *hMSH2* and *hMLH1*), ataxia telangiectasia (*ATM*), and in FAP (Table 70-7) (296–299). In the absence of syndromic cancer, the presence of  $\geq 3$  first-degree relatives with pancreatic cancer is associated with a 40% lifetime risk for that disease, suggesting that there are other forms of this disease yet to be discovered.

**TABLE 70-7 Hereditary Syndromes Associated with Familial Pancreatic Cancer**

Syndrome	Germline Mutation	Lifetime Risk for Pancreatic Cancer (%)
Hereditary Pancreatitis	<i>PRSS1</i> (cationic trypsinogen)	25–40
Familial atypical multiple mole melanoma syndrome (FAMMM)	<i>p16/CDKN2A</i> (cell cycle inhibitor)	10–17
Hereditary breast and ovarian cancer	<i>BRCA2</i> (DNA repair)	5
Hereditary breast and ovarian cancer	<i>BRCA1</i> (DNA repair)	3.6
Peutz–Jeghers syndrome	<i>STK11/LKB1</i> (kinase)	11–36
Lynch syndrome	DNA MMR genes (DNA repair)	3.7
Familial adenomatous polyposis	<i>APC</i> (tumor suppressor gene)	~2
Three or more affected first-degree relatives	Undetermined	40

Adapted from reference (299).

Finding the germline mutations is a challenge, since relatively few cases of multigenerational transmission of familial pancreatic cancer have been documented, and complicating this further, there are no simple preventive measures one might use to reduce the mortality from this disease. Surveillance is also a challenge even in patients with a known elevated risk, as no approaches are known to be effective in reducing the high mortality in pancreatic cancer.

### 70.5.3 Genetics of Esophageal Carcinoma and Familial Esophageal Cancer

Esophageal cancer occurs in two major histological forms, squamous cell carcinoma and adenocarcinoma. Squamous cell carcinoma is thought to be due to environmental factors, and has a wide range of incidence on a geographical basis. Esophageal adenocarcinoma occurs principally in patients with Barrett esophagus, a metaplastic condition in which the normal squamous lining is replaced by columnar mucosa. This condition is caused by chronic gastroesophageal reflux disease, and although families with Barrett esophagus have been reported (300,301), most cases of Barrett esophagus are apparently sporadic (302). The familial Barrett esophagus cases typically present at a younger age and may contribute to esophageal adenocarcinoma not recognized to be familial. Multiple SNPs are associated with both Barrett esophagus and esophageal adenocarcinoma, but it appears that a multitude of genes interacting with the environment may be involved in familial aggregations (reviewed in (303)).

One rare entity, esophageal tylosis, or keratosis palmaris et plantaris, is characterized by diffuse hyperkeratosis of the squamous epithelium of the esophagus, as well as hyperkeratosis of the palms and soles. This disease, previously referred to as the Howel–Evans syndrome, is associated with squamous cell carcinoma of the esophagus at an average age of 45 years (304). The gene for this has been mapped to 17q23-ter in a single large family (305). A candidate gene called *downregulated in multiple cancers 1* (*DMC1*) has been found in this region of chromosome 17q, and its expression is reduced in a number of cancers (306).

### 70.5.4 Other GI Cancers

Gastrointestinal stromal tumors (GISTs) may occasionally be familial. In one large kindred, the risk for GISTs was linked to a deletion of codon 579 in exon 11 of the *KIT* gene. Somatic loss of the wild-type *KIT* allele was demonstrated in the tumor of one individual. Affected individuals responded to treatment with imatinib, which has inhibitory activity for the *KIT* receptor tyrosine kinase (307). In another kindred, three sisters had intestinal neurofibromatosis and developed five GISTs. A germline mutation in the *PDGFRA* gene (Y555C) was found. This mutation in the juxtamembrane domain leads to autophosphorylation and activation of the receptor, and is a putative cause of this familial tumor cluster (308).

Familial GI carcinoid tumors have been reported, are rare, and have yet to be linked convincingly to specific genetic loci, except for multiple endocrine neoplasia (MEN1) kindreds (309). MEN1 families have germline mutations in the *MENIN* gene, and some have increases in pancreatic islet cell tumors as a feature of the disease. Pancreatic islet cell tumors may also occur in the context of von Hippel–Lindau (*VHL*) germline mutations (310).

A patient has been described with homozygous mutations (c.2386-11A>G, creating a de novo splice site) in the spindle-assembly checkpoint gene, *BUB1B*; he developed multiple early-onset cancers of the papilla of Vater, followed by later-onset adenomas and invasive cancers of the colon and stomach. No other characteristic features were identified (311).

## Biographies

**C Richard Boland, MD**, is Chief of Gastroenterology at Baylor University Medical Center in Dallas, Texas. He received degrees from The University of Notre Dame and Yale Medical School. He has a career-long research interest in colon cancer, specifically focusing on the causes of colon cancer and familial cancer syndromes. He was a Fellow and Assistant Professor at UCSF (1978–1984), moving to the University of Michigan as Associate and Professor from 1984 to 1995, and Professor of Medicine and Chief of the GI Division at UCSD from 1995 to 2003. He moved to Baylor, Dallas, in 2003 to focus on research with both laboratory-based and clinical programs designed to accelerate the translation of basic concepts into the diagnosis, prevention, and treatment of colorectal cancer. Dr Boland has been funded continuously by the NIH since 1979, served on multiple NIH Study Sections, has published >300 papers, has been elected to the AAP, and has trained numerous postdoctoral fellows who have followed him into the study of colorectal cancer. He served as President of the AGA from 2011 to 2012. His clinical activities are focused upon the familial forms of gastrointestinal neoplasia.

**Barbara Jung, MD**, is a Gastroenterologist at Northwestern Medical Faculty Foundation and an Associate Professor in the Department of Medicine at Northwestern. She received her MD and Doctorate in Medicine in 1996 from the Ludwig-Maximilians University, Munich, Germany. After a postdoctoral fellowship at the Sidney Kimmel Cancer Center in San Diego, she joined UCSD's physician-scientist training pathway in 1999 where she completed a residency in Internal Medicine followed by a fellowship in Gastroenterology. In 2004, she became faculty at UCSD as an Assistant Professor. She was awarded a K08 grant in 2005 and became Assistant Program Director for the GI Fellowship Program in 2006. In 2010, she relocated to Northwestern University in Chicago, where she heads a laboratory focused on CRC signaling, biomarker identification and validation and immune targets for CRC treatments. Further, she established and leads a multidisciplinary, personalized high-risk GI cancer clinic.

**John M Carethers, MD**, is currently Professor and Chair of the Department of Internal Medicine at the University of Michigan. Dr Carethers is a trained gastroenterologist and physician-scientist who focuses his research in the area of hereditary colon cancer genetics. Dr Carethers received his BS degree in Biological Sciences with a minor in Chemistry from Wayne State University, and his MD with high distinction from the same institution. Dr Carethers did his internship and residency in Internal Medicine at Massachusetts General Hospital, followed by a fellowship in gastroenterology at the University of Michigan. He was then recruited to the University of California San Diego where he grew his laboratory-based research in the area of DNA mismatch repair and colorectal cancer pathogenesis. Prior to being recruited to the University of Michigan, he served as the Gastroenterology Division Chief at UC San Diego.

## Hemoglobinopathies and Thalassemias

*John Old*

National Haemoglobinopathy Reference Laboratory, Molecular Haematology,  
John Radcliffe Hospital, Oxford, UK

### 71.1 INTRODUCTION

The hemoglobinopathies and the thalassemia syndromes are a diverse group of inherited disorders of hemoglobin synthesis that result from the qualitative defects (hemoglobinopathies) or quantitative defects (thalassemia syndromes) in globin synthesis. As a group they are the most common and clinically significant single gene disorder in the world and pose a serious health problem in many countries. The only definitive cure for the hemoglobinopathies is bone marrow transplantation, and thus only supportive management is available for the treatment of the vast majority of severely affected patients. The methods of clinical management have improved considerably during the past few years and the life expectancy of affected individuals has been significantly increased with patients now surviving to the third to fifth decade. However, the treatment required is very expensive and is not a realistic means of controlling the disorders for many developing countries. Therefore, many countries, especially those with a high incidence of  $\beta$ -thalassemia, are applying an alternative method of control that involves screening the population for carriers, identifying couples at risk, and providing prenatal diagnosis.

This chapter outlines the structure, function, and biosynthesis of normal hemoglobin, and then discusses the current knowledge of the clinical diseases associated with the defects in globin synthesis, their molecular pathology, diagnosis, and treatment. A more detailed description of the thalassemia syndromes may be found in the comprehensive book by Weatherall and Clegg (1), and for hemoglobin variants, in the book edited by Steinberg and Nagel (2).

### 71.2 NORMAL HUMAN HEMOGLOBIN

Hemoglobin (Hb) is a tetramer with a molecular weight of 64,500. It consists of two  $\alpha$  and two non- $\alpha$  globin polypeptide chains, each of which has a single covalently bound heme group. Each of the four heme groups is

made up of an iron atom bound within a protoporphyrin IX ring.

In humans, there are six known different globin polypeptide chains that form a number of hemoglobin tetramers. The polypeptide chains are designated  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ ,  $\epsilon$ , and  $\zeta$ . The  $\alpha$ - and  $\zeta$ -chains consist of 141 amino acids, while the  $\beta$ -,  $\gamma$ -,  $\delta$ -, and  $\epsilon$ -chains have 146 residues. The  $\epsilon$ -,  $\gamma$ -, and  $\delta$ -chains are more similar to  $\beta$ -chains than to  $\alpha$ -chains, differing from  $\beta$  at 36, 39, and 10 positions, respectively, and are designated  $\beta$ -like chains. The  $\zeta$  chain is an  $\alpha$ -like globin and is found in embryonic erythrocytes together with  $\epsilon$ -globin.

The hemoglobin composition of erythrocyte lysates can be quantified by cellulose acetate and starch gel electrophoresis. These procedures have been replaced in many laboratories by isoelectric focusing (IEF), which gives a much better resolution of the different hemoglobins, or by high performance liquid chromatography (HPLC), which provides a quick chromatographic method with a degree of automation. Different hemoglobin tetramers, their structure, percentage in normal adult lysate, and conditions in which levels are increased, are seen in Table 71-1

Hb A ( $\alpha_2\beta_2$ ) is the major component of hemoglobin in normal adults, usually comprising about 97% of the total hemoglobin. The remainder is Hb A<sub>2</sub> ( $\alpha_2\delta_2$ ), which usually constitutes about 2–3% in normal individuals. Hb A<sub>2</sub> is increased in the majority of the  $\beta$ -thalassemias and megaloblastic anemias and decreased in iron deficiency and sideroblastic anemias.

Hb A<sub>1c</sub> differs from Hb A by the posttranslational addition of a glucose at the NH<sub>2</sub> terminus of the  $\beta$ -chain; hence the tetramer's structure is  $\alpha_2(\beta\text{-N-glucose})_2$ . The percentage of Hb A<sub>1c</sub> (5% in normals) is related to the intracellular concentration of glucose and the red cell life span. In diabetic patients, the concentration of Hb A<sub>1c</sub> is increased about twofold because of the elevated glucose concentration in their red cells.

**TABLE 71-1 Human Hemoglobins**

Hb	Stage of Development	Structure	Percentage in Adults	Conditions in which Increased
A	Adult	$\alpha_2\beta_2$	92	
A <sub>1c</sub>		$\alpha_2(\beta\text{-N-glucose})_2$	5	Diabetes mellitus
A <sub>2</sub>		$\alpha_2\delta_2$	2–3	$\beta$ -Thalassemia
H		$\beta_4$	0	Some $\alpha$ -thalassemias
F	Fetal	$\alpha_2\gamma_2$	<1	Newborn, $\delta\beta$ -, $\beta$ -thalassemia, HPFH and marrow stress
Bart's		$\gamma_4$	0	Some $\alpha$ -thalassemias
Gower I	Embryonic	$\zeta_2\varepsilon_2$	0	Early embryos (<8 weeks)
Gower II	Embryonic	$\alpha_2\varepsilon_2$	0	Early embryos (>8 weeks)
Portland	Embryonic	$\zeta_2\gamma_2$	0	(<8 weeks) and $\alpha^0$ -thalassemia (hydrops fetalis)

Hb F ( $\alpha_2\gamma_2$ ), fetal hemoglobin, comprises the bulk of hemoglobin (50–85%) in human newborns, but declines rapidly after birth, reaching concentrations of 10–15% by 4 months of age. Subsequently, the decline is slower and adult levels of less than 1% are reached by 3–4 years of age. Fetal hemoglobin may be increased in  $\beta$ - and  $\delta\beta$ -thalassemia, hereditary persistence of fetal hemoglobin (HPFH), D1 trisomy, some cases of thyrotoxicosis, megaloblastic and aplastic anemias, leukemia and various malignancies involving marrow, sickle-cell anemia, and during pregnancy. Hb F is quantified by alkali resistance, electrophoresis, column chromatography, or HPLC. Hb F is heterogeneous because of the presence of two types of  $\gamma$ -globin chains, only differing in their composition at position 136. Those that contain glycine at this position are called  $G\gamma$ -chains and those with alanine at this position are called  $A\gamma$ -chains.

Hbs Gower I ( $\zeta_2\varepsilon_2$ ), Gower II ( $\alpha_2\varepsilon_2$ ), and Portland ( $\zeta_2\gamma_2$ ) are embryonic hemoglobins synthesized in the yolk sac before 8 weeks of gestation. At 4–5 weeks of gestation, a decrease in  $\zeta$ - and  $\varepsilon$ -chain production occurs, together with a compensating increase in  $\alpha$ - and  $\gamma$ -chain production. At this stage of gestation  $\beta$ -chain synthesis in reticulocytes accounts for 4% of non- $\alpha$ -chain synthesis and gradually increases thereafter. Then at around 8 weeks of gestation, the site of hemoglobin synthesis changes to the fetal liver, which produces Hb F plus a small amount of Hb A. At 18 weeks gestation, the liver is progressively replaced by bone marrow as the major site of red cell production and there is a gradual switch from Hb F to Hb A synthesis. The mechanism for this switch from Hb F to Hb A has been the subject of intense research for a number of years because of the therapeutic implications of increasing the amount of Hb F in affected patients with  $\beta$ -thalassemia and sickle-cell disease.

Hb H and Hb Bart's are tetramers of  $\beta$ - and  $\gamma$ -chains, respectively, and both function very poorly in transporting oxygen. These two hemoglobins may be increased in some types of  $\alpha$ -thalassemia in which the deficiency of  $\alpha$ -globin chains is sufficient to allow the production of unpaired  $\beta$ -like globin chains into soluble tetramers.

### 71.2.1 Primary and Secondary Structures

The primary structure of each globin chain is its amino acid sequence; it is composed of 141 amino acids in  $\alpha$ - and  $\zeta$ -chains and 146 amino acids in  $\beta$ -,  $\gamma$ -,  $\delta$ -, and  $\varepsilon$ -chains. The primary structure of  $\alpha$ - and  $\beta$ -chains is shown in [Figure 71-1](#).

The relationship between adjacent amino acids along the chain enables interactions that can result in one of two basic configurations of secondary structure: the  $\alpha$ -helix or  $\beta$ -pleated sheet. The  $\alpha$ -helix, stabilized by hydrogen bonding between carbonyl and amino groups, has 3.6 amino acid residues per turn. About 75% of hemoglobin in its native state is in the  $\alpha$ -helix form, as shown in [Figure 71-1](#). The  $\beta$ -pleated sheet configuration predominates in other molecules, such as immunoglobulins and chymotrypsin.

At specific locations in the hemoglobin subunits, the rodlike  $\alpha$ -helix is interrupted by nonhelical segments that allow folding of the amino acid chain. On X-ray crystallography, the confirmations of  $\alpha$ - and  $\beta$ -hemoglobin subunits are seen to be similar. The  $\beta$ -globin chain has eight helical segments, A through H, and the secondary structure of the  $\alpha$ -globin corresponds to that of the  $\beta$ -globin except for the absence of residues forming the D helical region see ([Figure 71-1](#)). The histidine residue at position 8 of the F helical segment (F8) is linked covalently to the heme iron molecule. This histidine residue is located at position 87 in the  $\alpha$ -chain and 92 in the  $\beta$ -chain, and mutations altering it have important pathologic consequences. Amino acids with charged side groups, for example, lysine, arginine, and glutamic acid, lie on the external surface, while uncharged residues tend to be oriented toward the interior of the molecule.

### 71.2.2 Tertiary and Quaternary Structures

Tertiary structure refers to the configuration of a protein subunit in three-dimensional space, while quaternary structure refers to the relationships of the four subunits of hemoglobin to each other. The hemoglobin tetramer has been shown by X-ray crystallography to be an oblate spheroid with a diameter of 5.5 nm and a

single axis of symmetry. The globin chains are folded so that the four heme groups are in surface clefts equidistant from each other. The four subunits forming the tetramers are labeled  $\alpha_1$ ,  $\alpha_2$ ,  $\beta_1$ , and  $\beta_2$ . While there is no contact between the two  $\beta$ -chains, each  $\alpha$ -chain touches both  $\beta$ -chains. Bonds across the  $\alpha_1\beta_1$  interface are firmer than those at the  $\alpha_1\beta_2$  interface, and changes from oxy- to deoxyhemoglobin involve more extensive movement at the  $\alpha_1\beta_2$  interface. The quaternary structure changes markedly in going from oxy- to deoxyhemoglobin, and this accounts for many of the observed changes in physical properties. Hemoglobin mutations resulting in amino acid substitutions at these points can markedly alter specific functional properties.

### 71.2.3 Functional Properties

For hemoglobin to fulfill its physiologic role, it must bind oxygen with a certain affinity. One measure of oxygen affinity is  $P_{50}$ , or the partial pressure of oxygen in millimeters of Hg that is required for 50% saturation of hemoglobin: a hemoglobin with increased  $P_{50}$  has decreased oxygen affinity (Figure 71-2). Oxygen affinity is also affected by a number of environmental factors including temperature, pH, organic phosphate concentration, and  $p\text{CO}_2$  see (Figure 71-2).

The sigmoidal shape of the oxyhemoglobin dissociation curve reflects heme–heme interaction; that is, successive oxygenation of each heme group in the tetramer increases the oxygen affinity of the remaining unoxygenated heme groups. The basis of heme–heme interaction is the decrease in the atomic radius of the heme iron that occurs with oxygenation, allowing the iron atom to fit into the plane of the porphyrin ring. This alteration is amplified by a series of conformational changes that affect the other heme groups. The resulting sigmoidal oxyhemoglobin dissociation curve has great physiologic importance because it enables large amounts of oxygen to be bound or released with a small increase or decrease in oxygen tension. In contrast to Hb A, Hb H ( $\beta_4$ ) and Hb Bart's ( $\gamma_4$ ) lack subunit interaction and have a hyperbolic rather than a sigmoidal oxyhemoglobin dissociation curve, which prevents oxygen release at physiologic oxygen tensions.

The Bohr effect is a change in oxygen affinity of hemoglobin with a change in pH. This effect is beneficial at the tissue level where the lower pH decreases oxygen affinity and promotes oxygen release see (Figure 71-2). Oxygen uptake in the lungs is enhanced by the opposite changes in pH and  $p\text{CO}_2$ .

Red cells have unusually high concentrations of 2,3-diphosphoglycerate (2,3-DPG). One molecule of 2,3-DPG sits in a pocket in deoxyhemoglobin bound to specific  $\beta$ -chain residues (1, 2, 82, and 143 of both  $\beta$ -chains). The importance of the binding is that 2,3-DPG stabilizes the deoxy form of hemoglobin in preference to the oxy form, thereby lowering the oxygen

**FIGURE 71-2** The oxyhemoglobin dissociation curve and effect of different factors on oxygen affinity.

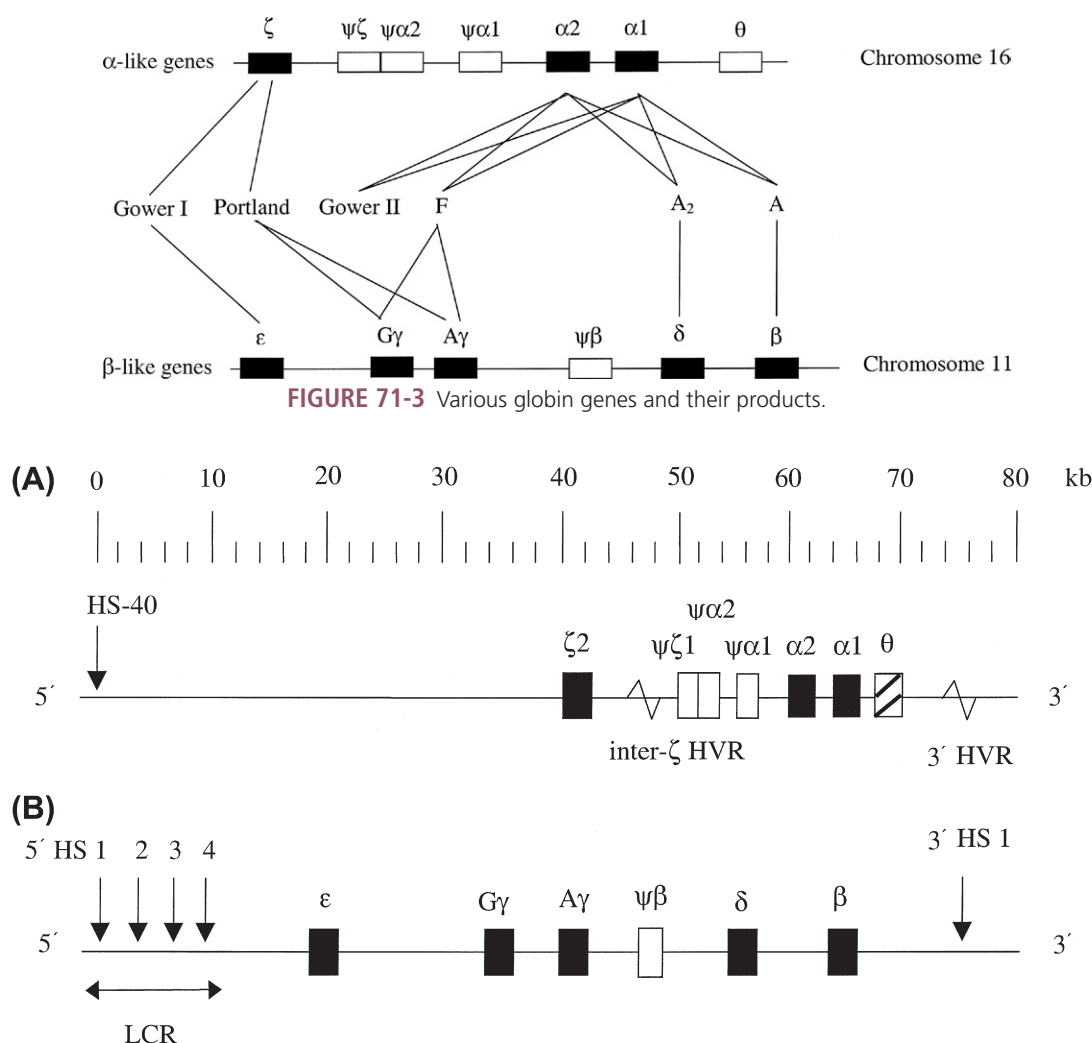

affinity of the molecule. The  $\gamma$ -chain of Hb F lacks the  $\beta^{143}$  histidine residue, and the resultant decrease in binding of 2,3-DPG to Hb F accounts for the increased oxygen affinity of fetal red cells compared with that of adult red cells.

## 71.3 HEMOGLOBIN BIOSYNTHESIS

### 71.3.1 Genetics

In humans there are eight different genetic loci that code for the six types of globin chains. In addition, there are at least four pseudogenes that have sequences similar to other globin genes but differ in that they are not expressed into globin proteins. A schematic representation of the interaction of the products of these genes is shown in Figure 71-3. Normally, globin tetramers are formed of two  $\alpha$  or  $\alpha$ -like chains and two  $\beta$  or  $\beta$ -like chains; since humans are diploid, that is, have a pair of each nonsex chromosome or autosome, they have two genes for each autosomal locus. Thus, as there are two loci encoding the structure of the  $\alpha$ -globin chain, there are four  $\alpha$ -chain genes. In contrast, there is only a single  $\beta$ -globin locus and, therefore, two  $\beta$ -genes see (Figure 71-3). The relative numbers of  $\alpha$ - and  $\beta$ -loci are important in understanding the different inheritance patterns of  $\alpha$ - and  $\beta$ -thalassemias, as well as the different relative amounts of variant hemoglobins in individuals carrying a variant  $\alpha$ - or  $\beta$ -globin gene. These quantitative differences correlate directly with the clinical severity of the various disorders.

The  $\beta$ -like globin genes form a linked cluster on the short arm of chromosome 11 (11p15.5), spread over a region of approximately 60 kilobases (kb), as depicted in Figure 71-4. There are five functional genes, arranged in the order of their developmental expression: 5'- $\epsilon$ - $\gamma$ - $\gamma$ - $\psi\beta$ - $\delta$ - $\beta$ -3'. The pseudogene ( $\psi\beta$ ) has sequences similar to

**FIGURE 71-4** Globin genes complexes. (A) β-Gene complex on chromosome 11. (B) α-Gene complex on 16. Distances along the chromosome are measured in kilobases (kb) at the top.

the β-gene, but differs in having altered sequences that prevent its expression and the production of functional globin chains. Each of the genes contains two intervening sequences (IVSs) that interrupt the coding sequence at the junctions of the codons for amino acids 30–31 and 104–105. The first IVS is 122–130 base pairs (bp), while the second is 850–904 bp in length. The globin gene sequences comprise only about 7 kb of the 60 kb of DNA in the β-gene region, while the remaining 53 kb are flanking sequences that contain sequences with specific regulatory roles. These include the locus control region, enhancer sequences, and the promoter regions of the globin genes.

The β-locus control region or LCR-β is found in a cluster of DNase I hypersensitive sites 6–18 kb 5' to the ε-globin gene. The LCR-β establishes a transcriptionally active domain spanning the entire β-globin gene cluster, allowing a high level of erythroid-specific expression of the genes. Transcription is dependent on the promoter regions of these genes becoming opposed to the LCR-β in association with the binding of a variety of regulatory

proteins consisting of both tissue-specific and ubiquitous transcription factors. The precise mechanism of the developmental switches of gene expression from ε to γ and from γ to β remains to be fully understood, but is known to be complex with respect to both gene silencing and gene competition for the LCR sequences.

Erythroid cells have been shown to contain a variety of erythroid-specific transcription factors, the most important being GATA-1 and NF-E2. GATA-1 belongs to a family of proteins recognizing the consensus sequence (T/A)GATA(A/G), and acts as a tissue-specific activator of transcription with binding sites both in the locus control regions and in the promoters and 32' flanking regions of the globin genes. NF-E2 binding sites have been identified in both the β- and α-locus control regions. Aberrant binding of GATA-1 to a mutant site has been implicated as the cause of one type of HPFH.

The α-like genes form a cluster on the tip of chromosome 16 at position 16p13.3 and are arranged in the order 5'-ε-ζ-ψζ-ψα2-ψα1-α2-α1-θ-3'. The cluster contains three functional genes (two α-genes that are 3.6 kb apart

and one  $\zeta$ -gene), three pseudogenes ( $\psi\zeta$ ,  $\psi\alpha 1$  and  $\psi\alpha 2$ ), and one gene of undetermined function ( $\theta$ ) as depicted in Figure 71-4. Unlike the pseudogenes, the  $\theta$ -gene does not contain any apparent defects in its sequence that would prevent its expression. In each case about 4kb separate the  $\zeta 1$ ,  $\psi\alpha 1$ ,  $\alpha 2$ , and  $\alpha 1$  loci, suggesting the existence of discrete duplication units in the DNA. The two  $\alpha$ -genes are the result of a duplication that took place about 60 million years ago. The  $\alpha$ -genes have smaller IVSs than are found in the  $\beta$ -like genes; IVS-I contains 114bp, while IVS-II contains 132bp. There is an  $\alpha$ -globin control region called HS-40 for the  $\alpha$ -globin gene cluster that is a nuclease-hypersensitive site analogous to LCR- $\beta$ , although its mechanism of action is different. Deletion of the LCR- $\alpha$  causes  $\alpha$ -thalassemia by inactivation of the adjacent intact  $\alpha$ -globin genes. The  $\alpha$ -gene cluster also contains several hypervariable repetitive minisatellite sequences (HVRs). These are the 5'-HVR, located 70kb upstream of the  $\zeta 2$ -gene; the inter- $\zeta$  HVR, between the  $\zeta 2$ - and  $\psi\zeta 1$ -genes; the intra- $\zeta$  HVR, within the introns of the  $\zeta 2$ - and  $\psi\zeta 1$ -genes; and the 3'-HVR, positioned at the 3' end of the cluster.

### 71.3.2 Ontogeny

The globin genes are expressed at different times and in different relative amounts during human development (Figure 71-5). The sequence of appearance of the various globin chains is helpful in understanding the timing of onset of clinical manifestations of the hemoglobinopathies and thalassemias. For example, a deficiency of  $\alpha$ - or  $\gamma$ -chain synthesis and  $\alpha$ - or  $\gamma$ -chain variants with abnormal functions should be observed at birth, while a deficiency of  $\beta$ -chains may not cause symptoms until several months of age. Finally, levels of  $\beta$ -chain variants, such as Hb S, progressively increase over the first months, so that

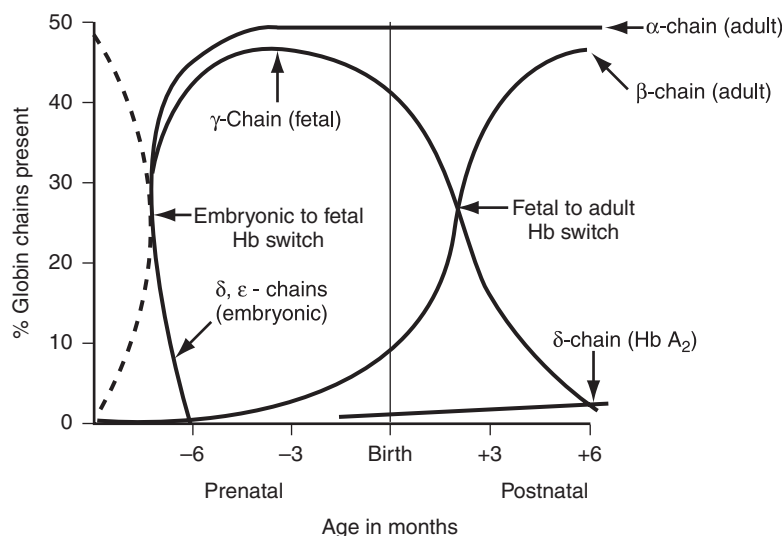

the onset of clinical manifestations may be delayed until the latter half of the first year of life.

### 71.3.3 Globin Biosynthesis

Each globin gene consists of a 5' promoter region, cap site, a 5' untranslated region (5' UTR), initiation codon, exon 1, intron 1 or IVS-I, exon 2, intron 2 or IVS-II, exon 3, termination codon, a 3' UTR, and a poly A signal (AATAAA). The gene is transcribed to produce messenger RNA precursor (pre-mRNA) (Figure 71-6), which starts at the cap site (3) nucleotides from the initiation codon and ends past the poly A site where the poly A tail is attached. The pre-mRNA molecule is then processed, undergoing excision of the IVSs and splicing of the three exon sequences.

Further processing occurs at each end of this RNA molecule. At the 5' end, guanosine is added in a special triphosphate linkage, and this guanosine and the next two nucleotides are then methylated. These 5' end modifications are called capping and methylation and while their function is not completely known, they have been shown to be vital for the initiation of translation of many mRNAs, including globin mRNAs. The 3' end modification involves the addition of about 150 adenylic acid nucleotides [poly(A)]. Poly(A) addition may also be important for the transport of mRNA to the cytoplasm and its subsequent stability. With aging of the mRNA, the poly(A) "tail" shortens.

Once the processed mRNA has been transported to the cytoplasm, it binds to ribosomes. The first step in translation (initiation) requires the binding of mRNA to the two ribosome subunits, amino acyl-tRNA, guanosine triphosphate, and protein initiation factors. Initiation occurs at the 5', or capped, end of mRNA that corresponds to the  $\text{NH}_2$ -terminal end of the globin chain.

**FIGURE 71-5** Qualitative and quantitative changes in globin chains during human development. Note that the percentage of  $\beta$ -chains accumulated in early fetal development is much less than the percentage of  $\beta$ -chains synthesized during fetal development. (Modified from Bunn, H. F.; Forget, B. G.; Ranney, H. M. *Hemoglobin Structure*. In *Human Hemoglobins*; WB Saunders: Philadelphia, 1977; p 4, with permission.)

Protein synthesis then proceeds toward the COOH-terminal end. Four to six chains of varying length (nascent chains) undergo translation on the same mRNA simultaneously. When these nascent chains have attained full length, a termination codon is reached. Since no tRNA is available for decoding this codon, polypeptide synthesis stops and, with the assistance of protein termination factors, the polypeptide chain is released from the ribosome and its mRNA. About one-third of the mature mRNA sequence is not used for translation, but these untranslated nucleotides, which are located at both ends of the molecule, may have other regulatory functions.

The protein chain assumes its secondary and tertiary structures because of interactions resulting from its amino acid sequence. Next, heme is bound and, in combination with other polypeptide subunits, the quaternary hemoglobin molecule is formed. These steps are shown in Figure 71-6.

## 71.4 HUMAN HEMOGLOBIN VARIANTS

### 71.4.1 Molecular Etiology

Abnormal hemoglobins result from mutations that change the sequence or number of nucleotides within the globin gene involved, or more rarely, from mispairing and crossover between two like genes during meiosis, creating a fusion protein of both gene sequences.

Mutation can cause substitution, addition, or deletion of one or more amino acids in the polypeptide sequence of the affected globin (Table 71-2).

Single base changes can result in single amino acid substitutions (e.g. Hb S ( $\beta 6$  Glu→Val)), shortened chains due to premature termination of translation (e.g. Hb McKees Rocks ( $\beta 145$  Tyr→Termination)), or elongated chains. Elongated chains result when the termination codon undergoes a mutation to a codon for an amino acid, such as UAA→CAA ( $\alpha 142$ ) in Hb Constant Spring. Two other elongated chains are Hb Icaria and Hb Koya Dora, both of which also have 31 additional residues and differ from Hb Constant Spring only at residue 142.

Single base deletions or additions can cause a frame-shift in the normal reading process. For example, in the variant Hb Wayne, a single base deletion (-A) at codon  $\alpha 139$  causes the subsequent sequence of two codons, the termination codon TAA and the 3' UTR to be read out of phase for seven triplets until a new terminating codon (TAG) is encountered.

Deletions of three, or multiples of three, nucleotides in the DNA cause deletions of one or more amino acids. It is interesting that of 13 examples of this type, all are  $\beta$ -chain variants, including Hb Leiden ( $\beta 6$  or 7 Glu→0) and Hb Gun Hill ( $\beta 91-95$  [Leu-His-Cys-Asp-Lys]→0). Deletions of segments of genes may be due to nonhomologous crossing over after mispairing in meiosis. This mechanism accounts for the Hb Lepore globins ( $\delta\beta$  fusion

**FIGURE 71-6** Steps involved in hemoglobin biosynthesis. Understanding of the order and function of various steps is incomplete.

**TABLE 71-2 Molecular Basis of the Hb Variants**

Mutation	Example Hb		Clinical Manifestation	Molecular Basis (Presumed)
Nucleotide base substitutions for				
One amino acid	Hb S	$\beta 6\text{Glu} \rightarrow \text{Val}$	Sickling	$\beta\text{:Cd 6 GAG} \rightarrow \text{GTG}$
Two amino acids	Hb C-Harlem	$\beta 6\text{Glu} \rightarrow \text{Val} + \beta 73\text{Asp} \rightarrow \text{Asn}$	Sickling	$\beta\text{:Cd 6 GAG} \rightarrow \text{GTG}$ & $\beta\text{:Cd 73 GAT} \rightarrow \text{AAT}$
Termination	Hb McKees Rocks	$\beta 145 \text{ Tyr} \rightarrow \text{Termination}$	Increased oxygen affinity and polycythemia	$\beta\text{:Cd 145 TAT} \rightarrow \text{TAA}$
Amino acid instead of termination	Hb Constant Spring	$\alpha 2\text{:142 Termination} \rightarrow \text{Gln}$	Decreased synthesis (thalassemia-like)	$\alpha 2\text{:Cd 142 TAA} \rightarrow \text{AAA}$
Nucleotide base deletions				
Single base deletion $\rightarrow$ frameshift	Hb Wayne	$\alpha 2\text{:139-146 Lys-Tyr-Arg} \rightarrow \text{Asn} + 7 \text{ residues}$	Normal	$\alpha 2\text{:Cd 139 (-A)}$
Triplet deletion $\rightarrow$ single amino acid	Hb Leiden	$\beta 6 \text{ or } 7 \text{ Glu} \rightarrow 0$	Unstable	$\beta\text{:Cd 6 or 7 (-GAG)}$
Multiple codon	Hb Gun Hill	$\beta 91-95 \text{ Leu-His-Cys-Asp-Lys} \rightarrow 0$	Unstable	$\beta\text{:Cd 91-95 (-15 bp)}$
Crossover	Hb Lepore	$\delta\beta$ -fusion with segments of $\delta$ and $\beta$ lost	Decreased synthesis (thalassemia-like)	$\delta\beta\text{:7.4 kb deletion}$
Nucleotide base additions				
Two bases added $\rightarrow$ frameshift	Hb Cranston	$\beta 144 \text{ Tyr-His} \rightarrow \text{Ser-Ile-Thr}$	Unstable	$\beta\text{:Cd 144/145 +CT}$
Multiple codon	Hb Grady	$\alpha 118 (+\text{Glu-Phe-Thr})$	Normal	$\alpha 2 \text{ or } \alpha 1\text{:Cd 118/119 (+9 bp)}$

**TABLE 71-3 Numbers of Known Hemoglobin Variants**

Type	Number
$\alpha$ Chain variants (total)	378
$\beta$ Chain variants (total)	529
$\gamma$ Chain variants (total)	87
$\delta$ Chain variants (total)	50
Variants with two amino acid replacements	19
Variants with hybrid chains	12
Variants with elongated chains	13
Variants with deletions, insertions and deletions/insertions	27
$\alpha$ Chain variants with the same mutation on both the $\alpha 1$ and $\alpha 2$ gene	14
$\alpha$ Chain variants with a different mutation on the $\alpha 1$ and $\alpha 2$ gene	2

chains), the anti-Lepore globins ( $\beta\delta$  fusion chains), and Hb Kenya globin ( $\gamma\beta$  fusion chain).

### 71.4.2 Known Variants

The numbers of known hemoglobin variants resulting from changes in the nucleotide base number or sequence in DNA are shown in Table 71-3. An updated listing is available on the Internet through the globin gene server Web site (HbVar): <http://globin.cse.psu.edu> (4). A total of 1044 variants are listed, most of these detected by gel electrophoresis or HPLC, which separate hemoglobins on the basis of charge differences resulting from the

amino acid substitutions. Since many mutations that do not change the protein's charge are not detected by this method, many undetected hemoglobin variants must still exist in the population. Hb variants were originally characterized by the identification of the substituted amino acid by peptide analysis, but now as new variants are added to the list, the substituted amino acid is identified from the changed gene sequence or by mass spectrometry. The number of  $\beta$ -chain variants (529) is more than that of  $\alpha$ -variants (378), even though there are two  $\alpha$ -loci compared to a single  $\beta$ -locus. The majority of the  $\alpha$ -chain variants have arisen from one mutation on either the  $\alpha 1$ -gene or the  $\alpha 2$ -gene. For  $\alpha$ -chain variants characterized by protein analysis techniques, the particular  $\alpha$ -gene carrying the variant is not known. However, gene-specific polymerase chain reaction (PCR)-based sequencing allows the identification of the variant  $\alpha$ -globin gene, and such studies have revealed that fourteen  $\alpha$ -chain variants result from the identical mutation on either of the two  $\alpha$ -genes, with the percentage Hb variant expressed by the  $\alpha 2$ -gene mutation being higher than that of the  $\alpha 1$ -gene mutation (5). Interestingly, DNA sequencing has also revealed that at least three  $\alpha$ -chain variants have arisen by different mutations, for example, Hb J-Broussais has arisen by the mutation G  $\rightarrow$  T on codon 90 of the  $\alpha 2$ -gene and G  $\rightarrow$  C on codon 90 of the  $\alpha 1$ -gene.

Table 71-4 compares the properties of the hemoglobin variants according to the different types of abnormal globin chains. The vast majority of these variants arise from a single base substitution, which results in a single amino acid substitution. Many of these substitutions are

**TABLE 71-4 Comparison of the Properties of Hb Variants**

Globin Chain	Total Variants	Clinically Silent (%)	Unstable (%)	Increased Oxygen Affinity (%)	Decreased Oxygen Affinity (%)	Ferric Hb (%)	Sickling (%)	Thalassemic (%)
$\alpha$	378	()	93 (26)	63 (17)	14 (4)	1 (<1)	0 (0)	38 (10)

clinically silent, including some of those that produce abnormal physical properties in the variant hemoglobin, and have been detected only through population screening. The amino acid substitutions can cause a number of abnormal physical properties. These are (i) instability of the tetramer; (ii) deformity of the three-dimensional structure; (iii) inhibition of ferric iron reduction; (iv) alteration of the residues that interact with heme, with 2,3-DPG, or at the  $\alpha$ - $\beta$  subunit contact site; or (v) abnormality of other properties of the molecule. The varieties of clinical phenotypes that arise from these abnormal physical properties are listed in Table 71-5.

The location of the amino acid changed by the mutation can often be correlated with the resultant phenotype. Unstable hemoglobin variants arise from several types of changes in the primary sequence that affects the secondary, tertiary, or quaternary structure. These substitutions tend to be at residues in the interior of the molecule, at contact points between chains, at residues that interact with the heme groups, or when a proline residue replaces another amino acid within an  $\alpha$ -helical region (Hb Genova [ $\beta$ 28(B10)Leu→Pro], Hb Abraham Lincoln [ $\beta$ 32(B14)Leu→Pro]), resulting in disruption of the helix. Hb Philly [ $\beta$ 35(C1)Tyr→Phe] is also unstable, secondary to a missing hydrogen bond normally found between the  $\alpha_1$  and  $\beta_1$  subunits. Many other unstable hemoglobins are the result of mutations affecting residues that bind

heme or are in the hydrophobic heme cleft, for example, Hb Gun Hill [ $\beta$ 91–95 (Leu-His-Cys-Asp-Lys)→0] and Hb Hammersmith ( $\beta$ 42 Phe→Ser).

Substitutions on the surface of the molecule usually do not affect tertiary structure or heme–heme interaction, but they may permit molecular interactions that decrease solubility under certain conditions [Hb S  $\beta$ 6 Glu→Val]. Substitution of tyrosine for either of the histidines that bind the iron molecule (E7 or F8) results in increased stability of the ferric (oxidized) iron state seen in M hemoglobins, M-Boston [ $\alpha$ 58(E7)His→Tyr], and M-Iwate [ $\beta$ 87(F8)His→Tyr]. Substitution at an  $\alpha_1\beta_1$  subunit contact point, such as  $\beta$ 99, can disturb heme–heme interactions causing increased oxygen affinity and polycythemia, as with Hb Kempsey [ $\beta$ 99(G1)Asp→Asn].

Although most hemoglobin variants are synthesized at a normal rate, several are associated with quantitative as well as qualitative abnormalities. One example, Hb E ( $\beta$ 26 Glu→Lys), is the second most common hemoglobinopathy worldwide and is associated predominantly with Southeast Asian populations. Both the heterozygous and homozygous states are associated with red cell microcytosis and hypochromia, and the thalassemic phenotype of the  $\beta^E$  gene is linked to activation of a cryptic donor splice site by the codon 26 mutation. Competition between the normal and abnormal alternative splice sites reduces  $\beta^E$ -mRNA production, resulting in a very mild  $\beta$ -thalassemia phenotype. Individuals homozygous for Hb E have a very mild disorder, being only slightly anemic with red cell indices similar to those of  $\beta$ -thalassemia trait. However, for reasons still not fully understood, Hb E trait combines with  $\beta$ -thalassemia trait to produce a serious thalassemic disorder, compound heterozygotes having a variable clinical picture ranging from thalassemia intermedia to homozygous  $\beta$ -thalassemia.

### 71.4.3 Inheritance of Hemoglobinopathies

Heterozygotes for a hemoglobin containing an abnormal  $\beta$ -globin chain have an abnormal as well as a normal  $\beta$ -gene at that locus, and their status is often described by the term “trait.” Since most variants are rare, they usually occur in the heterozygous state and, if they cause clinical symptoms, are examples of autosomal

dominant conditions. When both alleles code for the same common  $\beta$ -variant, the individual is then homozygous and is said to have the “disease” state. The most commonly encountered variants in the homozygous state are Hb S, C, D, and E and their phenotypes are listed in Table 71-6.

It should be noted that the term “sickle-cell disease” is often used to describe a similar phenotype that is seen when any of several genotypes (SS, SC, S/ $\beta$ -thalassemia, S/D-Punjab, or S/O-Arab) are exposed to a

certain environment (hypoxia), as listed in Table 71-6. Furthermore, under conditions of severe hypoxia a person with the AS genotype or “trait” can also manifest symptoms of the sickle-cell “disease” phenotype. This distinction between the genotype (homozygous and heterozygous) and the phenotype (trait and disease) is an important one. For these reasons, the patterns of inheritance of hemoglobin variants are more precisely expressed in terms of genotypes than in terms of phenotypes.

**TABLE 71-6** Phenotypes of Thalassemias, Sickle-cell Disorders and Various Hb Variant/Thalassemia Interactions

Type	Phenotype	DNA Diagnosis
<b>1. Homozygous states</b>		
$\alpha^0$ -Thalassemia (—/—)	Hb Bart's hydrops fetalis	Gap-PCR, MLPA
$\alpha^+$ -Thalassemia ( $-\alpha/-\alpha$ )	No clinical problems	Gap-PCR, MLPA
$\alpha^+$ -Thalassemia ( $\alpha^T\alpha/\alpha^T\alpha$ )	Hb H disease	ASO, sequencing
<b><math>\beta</math>-Thalassemia</b>		
$\beta^0$ or severe $\beta^+$ mutation	Thalassemia major	ASO, ARMS, sequencing
Mild $\beta^{++}$ mutation	Thalassemia intermedia	ASO, ARMS, sequencing
$\delta\beta^0$ -Thalassemia	Thalassemia intermedia	Gap-PCR, MLPA
HPFH	No clinical problems	Gap-PCR, MLPA
Hb Lepore	Variable: intermedia to major	Gap-PCR
Hb S	Sickle-cell disease	RE-PCR, ASO, ARMS
Hb C	Moderate anemia and splenomegaly	ASO, ARMS
Hb D-Punjab	No clinical problems	RE-PCR, ASO, ARMS
Hb E	No clinical problems	ASO, ARMS
<b>2. Compound heterozygous states</b>		
$\alpha^0$ -thal/ $\alpha^+$ -thal (—/— $\alpha$ )	Hb H disease	Gap-PCR, MLPA
$\alpha^0$ -thal/ $\alpha^+$ -thal (—/— $\alpha^T\alpha$ )	Severe Hb H disease or H hydrops	Gap-PCR, MLPA
$\beta^0$ -thal/severe $\beta^+$ -thal	Thalassemia major	ASO, ARMS, sequencing
Mild $\beta^+/\beta^0$ or severe $\beta^+$ -thal	Variable: intermedia to major	ASO, ARMS, sequencing
$\delta\beta^0$ -thal/ $\beta^0$ or severe $\beta^+$ -thal	Variable: intermedia to major	Gap-PCR, MLPA, as for $\beta^+/\beta^0$
$\delta\beta^0$ -thal/mild $\beta^+$ -thal	Mild thalassemia intermedia	Gap-PCR, MLPA, as for $\beta^+/\beta^0$
$\delta\beta^0$ -thal/Hb Lepore	Thalassemia intermedia	Gap-PCR, MLPA,
$\alpha\alpha/\beta^0$ or severe $\beta^+$ -thal	Mild thalassemia intermedia	Gap-PCR, as for $\beta^+/\beta^0$
Hb Lepore/ $\beta^0$ or severe $\beta^+$ -thal	Thalassemia major	Gap-PCR, MLPA, as for $\beta^+/\beta^0$
Hb C/ $\beta^0$ or severe $\beta^+$ -thal	Variable: $\beta$ -thal trait to intermedia	ASO, ARMS, sequencing
Hb C/mild $\beta^{++}$ -thal	No clinical problems	ASO, ARMS, sequencing
Hb D/ $\beta^0$ or severe $\beta^+$ -thal	No clinical problems	RE-PCR, ARMS, sequencing
Hb E/ $\beta^0$ or severe $\beta^+$ -thal	Variable: intermedia to major	ASO, ARMS, sequencing
Hb O-Arab/ $\beta^0$ -thal	Severe thalassemia intermedia	RE-PCR, ARMS, sequencing
Hb S/ $\beta^0$ or severe $\beta^+$ -thal	Sickle-cell disease	RE-PCR, ASO, ARMS
Hb S/mild $\beta^{++}$ -thal	Usually mild sickle-cell disease	RE-PCR, ASO, ARMS
Hb S/Hb C	Sickle-cell disease, variable severity	RE-PCR, ASO, ARMS
Hb S/Hb D-Punjab	Sickle-cell disease	RE-PCR, ASO, ARMS
Hb S/Hb O-Arab	Sickle-cell disease	RE-PCR, ASO, ARMS
Hb S/HPFH	Sickle-cell trait	RE-PCR, Gap-PCR, MLPA
<b>3. Hb E disorders</b>		
Hb E + $\alpha^0$ -thal/ $\alpha^+$ -thal (—/— $\alpha$ )	Hb AE Bart's disease see (Table 71-9)	Gap-PCR, ARMS,
Hb E + $\alpha^0$ -thal/ $\alpha^+$ -thal (—/— $\alpha^T\alpha$ )	Hb AE Bart's disease	Gap-PCR, ARMS, sequencing
Hb EE + $\alpha^+$ -thal/ $\alpha^+$ -thal ( $\alpha^T\alpha/\alpha^T\alpha$ )	Mild thalassemia intermedia	Gap-PCR, ARMS, sequencing
Hb EE + $\alpha^0$ -thal/ $\alpha^+$ -thal (—/— $\alpha$ )	Hb EF Bart's disease see (Table 71-9)	Gap-PCR, ARMS,
Hb EE + $\alpha^0$ -thal/ $\alpha^+$ -thal (—/— $\alpha^T\alpha$ )	Hb EF Bart's disease	Gap-PCR, ARMS, sequencing
Hb E/ $\beta^0$ + $\alpha^0$ -thal/ $\alpha^+$ -thal (—/— $\alpha$ )	Hb EF Bart's disease	Gap-PCR, ARMS, sequencing
Hb E/ $\beta^0$ + $\alpha^0$ -thal/ $\alpha^+$ -thal (—/— $\alpha^T\alpha$ )	Hb EF Bart's disease	Gap-PCR, ARMS, sequencing

Hb, hemoglobin; thal, thalassemia; HPFH, hereditary persistence of fetal hemoglobin; PCR, polymerase chain reaction; MLPA, multiplex ligation-dependent probe amplification; RE, restriction enzyme; ASO, allele specific oligonucleotide; ARMS, amplification refraction mutation system.

## 71.5 SICKLE-CELL ANEMIA AND RELATED DISORDERS

### 71.5.1 Molecular Basis and Geographical Distribution

The sickle-cell gene results from a point mutation at the second nucleotide of codon 6 of the  $\beta$ -globin gene. The base change of A to T causes the amino acid substitution of valine for glutamic acid (i.e. GAG to GTG); therefore, Hb S is  $\alpha_2\beta_2^{6 \text{ Glu} \rightarrow \text{Val}}$  ( $\beta^S$ ). The frequency of sickle trait (Hb AS) among United States blacks at birth is about 8%, and the incidence of sickle-cell anemia at birth should be around 0.16%, or 1 in 625 births. This contrasts with the higher carrier frequencies seen in some areas of equatorial Africa because of the protective advantage conferred by the carrier state against falciparum malaria (AS children have a relative resistance to malaria during early childhood, and are more likely to survive, breed, and pass on their genes). Hb S is known to occur at frequencies up to 20% in the Cameroons, Guinea, Zaire, Uganda, and Kenya. It also occurs at similar gene frequencies in the Quatif oases of eastern Saudi Arabia and parts of India. At lower gene frequencies of up to 5%, the sickle-cell gene has been reported in Nepal, in regions around the Mediterranean (e.g. Turkey, Lebanon, Syria, Greece, Portugal, and the coast of North Africa), in the Middle East and in Iran. The malaria hypothesis explains the distribution of Hb S in all these regions except those of the New World (United States, Caribbean islands, Brazil, etc.) and Europe. Hb S in the New World is found only in immigrants from malarious regions of the Old World and thus arrived in these regions by gene flow. Similarly, gene flow was responsible for the introduction of Hb S in the Mediterranean countries, by the slave trade in ancient times, and in European countries such as the United Kingdom by the voluntary population migration in the twentieth century.

### 71.5.2 Pathophysiology of Sickling

Substitution of valine for glutamic acid at the  $\beta 6$  residue causes a change on the surface of the deoxygenated  $\beta^S$  chain, which allows it to interact in a special way with other  $\beta$ -chains. This interaction results in the formation by  $\alpha_2\beta_2^S$  tetramers of a 14-stranded helical polymer of diameter 15–17 nm. The parallel alignment of these rod-like polymers, in turn, causes the sickle-shaped deformation of the erythrocytes. In sickle-cell anemia the sickling process may begin when the oxygen saturation of Hb S is decreased to 85%, but it does not occur in heterozygotes (Hb AS) until the oxygen saturation of hemoglobin is decreased to 40%. In addition to a decrease in oxygen tension, a reduction in pH or an increase in 2,3-DPG also promotes sickling. These factors probably interact in patients with sickle-cell anemia, since their blood normally has an increased 2,3-DPG concentration.

The viscosity of oxygenated sickle-cell blood is increased, primarily because of irreversibly sickled cells, and also because of increased gamma globulin levels. When the blood becomes deoxygenated, viscosity increases further because of the cellular rigidity that occurs with sickling. This, in turn, increases the exposure time of erythrocytes to a hypoxic environment, and the lower tissue pH decreases oxygen affinity, which further promotes sickling. The end result is occlusion of capillaries and small arteries and infarction of surrounding tissues. Deformed sickle cells also have a shorter survival time because of their increased mechanical fragility and damaged membranes, resulting in a more rapid red cell turnover and consequent anemia.

### 71.5.3 Clinical Aspects of Sickle-Cell Disease

As can be seen from Figure 71-6,  $\beta$ -chain production does not usually reach sufficient levels to cause symptoms until the second half of the first year of life. As higher concentrations of Hb S are reached in erythrocytes, the cells become susceptible to hemolysis and a progressive hemolytic anemia with splenomegaly is seen. The increased rate of erythropoiesis leads to erythroid marrow expansion and increased folic acid requirements. However, the two major problems for young children with SS disease are infections and vaso-occlusive crises.

Children with sickle-cell anemia have increased susceptibility to potentially life-threatening bacterial infections including sepsis and meningitis caused by *Streptococcus pneumoniae* and *Haemophilus influenzae*. The relative risk of sickle-cell anemia patients compared with that of normals for pneumococcal, *H. influenzae* and all bacterial meningitis is 579:1, 116:1, and 309:1, respectively. These patients are also susceptible to bacterial pneumonia (often *Pneumococcus*), osteomyelitis (*Salmonella* and *Staphylococcus*) (Figure 71-7), and urinary tract infections (*Escherichia coli* and *Klebsiella*). Increased susceptibility is also seen for *Shigella* and *Mycoplasma pneumoniae*. Several factors that contribute to this susceptibility are functional hyposplenism, impaired antibody response, decreased opsonization, impaired complement activation in the properdin pathway, and abnormal chemotaxis.

Bacterial infection is the most common reason for hospitalization of pediatric sickle-cell anemia patients and often leads to the diagnosis. Serious bacterial infections are seen in approximately one-third of children with sickle-cell anemia before 4 years of age. Infection, not crisis, is the most common cause of death in these children, although infections often precipitate crises.

Vaso-occlusive crises begin in infancy with dactylitis, or hand-and-foot syndrome see (Figure 71-7). Later crises may involve the periosteum, bones, or joints, resulting in infarction that must be differentiated from osteomyelitis and septic arthritis. Vaso-occlusive crises

**FIGURE 71-7** Radiographic changes in sickle-cell anemia. (A) Changes in the tibiae and fibulae secondary to *Salmonella osteomyelitis*. (B) Hand-and-foot syndrome with soft-tissue swelling and focal areas of cortical destruction and periosteal new bone formation. (Courtesy of Dr John Dorst.)

and sepsis are difficult to differentiate and often coexist in younger children.

Pulmonary crises with pleural pain and fever may be due to infection, in situ thrombosis, or embolism. Other clinical manifestations include splenic sequestration, abdominal and aplastic crises, cholelithiasis, hepatic infarcts, occlusion of cerebral vessels, ocular changes, hematuria, hyposthenuria, hyponatremia, priapism, and skin ulcers.

Sickle-cell disease has a broad spectrum of clinical severity. Because the  $\beta^S$ -gene has a stable single point mutation, the variability of clinical expression of sickle-cell disease is explained by the interaction of a number of factors, which can be genetic, cellular, or physiological. There are genetic factors that can be co-inherited with sickle-cell disease, such as  $\alpha$ -thalassemia and the determinants that increase Hb F (such as  $\beta$ -globin haplotypes), and those that interact with the sickle-cell trait (e.g. double heterozygosity for  $\beta$ -thalassemia, Hb C, Hb D-Punjab, or Hb O-Arab). The cellular factors include those that affect erythrocyte cell volume such as Hb concentration, pH and ion balance, and physiological factors such as vascular tone.

The effect of  $\alpha$ -thalassemia on the clinical picture of sickle-cell disease is complex.  $\alpha$ -Thalassemia lowers the mean cell volume (MCV) and the mean corpuscular hemoglobin concentration (MCHC). As the latter is one of the factors that determine the extent of polymerization of Hb S, the result of  $\alpha$ -thalassemia is a reduction in polymerization and a milder anemia. There is a reduction in hemolysis and fewer sickling-related manifestations such as leg ulceration and acute chest syndrome. However, the advantages of the inhibition of sickling are balanced by disadvantages of  $\alpha$ -thalassemia in causing a reduction in hemolysis and an increase in total hemoglobin. These effects result in an increase in blood viscosity, making patients more prone to painful crises and vaso-occlusive episodes such as a vascular necrosis.

Analysis of  $\beta^S$ -gene haplotypes has demonstrated four common patterns within African ethnic groups: the Benin, CAR (Central African Republic) or Bantu, Senegal, and Cameroon haplotypes. Although at least 17 different  $\beta^S$ -gene haplotypes have been identified, only these four haplotypes appear not to be related to each other by simple recombination events. Epidemiologic studies in Africa and the United States show that in SS patients, the presence of a CAR haplotype on one  $\beta^S$ -chromosome is associated with low Hb F levels and a higher risk of soft-tissue organ failure and early death. On the other hand, patients with the Senegal haplotype have higher levels of Hb F and less severe disease. The highest Hb F levels are exhibited in SS patients from eastern Saudi Arabia and India, resulting in a clinically benign disease. These patients are usually homozygous for a fifth  $\beta^S$ -gene haplotype, the Indian-Arab haplotype, indicating the Hb S mutation has occurred independently to the mutations in Africa. It is not clear in which direction the mutation traveled, originating in India and migrating to Arabia or vice versa.

The persistence of Hb F in adults inhibits the polymerization of Hb S as well as reduces the Hb S concentration. Indeed, patients doubly heterozygous for Hb S and the deletion form of HPFH have no clinically significant hematologic abnormalities despite having only Hb S and Hb F. Such compound heterozygotes have nearly normal red cells, each with 20–30% Hb F in a pancellular distribution.

### 71.5.4 Diagnosis

The peripheral blood smear of sickle-cell anemia patients may have normal-appearing, irreversibly sickled, target, and nucleated red cells. Howell-Jolly bodies and red cell fragments are also present, especially after functional asplenia develops (Table 71-8A). The clinical history of crises or severe infections with anemia, abnormal

red cell morphology on peripheral smear with a normal or elevated mean corpuscular volume (MCV), positive sickling test, and Hb S (greater than 80%) and Hb F on electrophoresis or HPLC, makes the diagnosis of sickle-cell anemia probable. Family studies indicating that both parents have the sickle-cell trait are helpful to exclude S/ $\beta^0$ -thalassemia and S/HPFH, although a definitive diagnosis is best made by DNA analysis for the Hb S mutation and the other possible interacting genotypes. In addition, sibs should also be tested to identify and treat previously undiagnosed cases.

### 71.5.5 Treatment

A number of antisickling agents have been tried to ameliorate sickle-cell disease and a number of new therapies have evolved from our improved understanding of the pathophysiology of sickle-cell disease (6). The three main approaches to therapy are (i) the chemical inhibition of Hb S polymerization to increase red cell hydration, (ii) reducing the MCHC by inhibiting potassium ion and water loss (e.g. with the antifungal agent clotrimazole), and (iii) the pharmacological induction of Hb F. Hb F concentrations are inversely related to morbidity in sickle-cell disease and the use of drugs that diminish Hb S polymerization by increasing the level of Hb F has been the most promising approach (7). Initially, cytotoxic agents such as 5-azacytadine were demonstrated to increase Hb F in patients, but then more benign drugs including hydroxyurea, erythropoietin, and short chain fatty acids such as butyrate were studied in sickle-cell anemia patients (7). The most successful of these agents has been hydroxyurea, which increases fetal hemoglobin production presumably through its effect in speeding up erythroid precursors through their maturation steps, the Hb level and the MCV, and reduces the frequency of painful crises. Hydroxyurea was approved 10 years ago specifically for the management of severe sickle-cell disease in adults and has now an established role in ameliorating the disease and improving life expectancy for most adult patients (8). The drug has also been shown to be effective in treating children with SS disease and adults with Hb S/ $\beta$ -thalassemia with beneficial effects (9).

The clinical management of sickle-cell anemia is basically supportive and prophylactic, involving prompt and effective analgesia, rehydration, antibiotics, and hospital admission as appropriate. Infections should be treated promptly with antibiotics. Newborn screening and close follow-up, especially early in life, has significantly improved survival. The clinical benefit of daily prophylactic penicillin in reducing the incidence of serious pneumococcal infections was demonstrated conclusively by the PROPS I study, and now represents standard practice. The associated anemia is usually tolerated well, but if folate deficiency occurs, the anemia becomes more severe and is associated with macrocytosis, hypersegmented granulocytes, and a decrease in the percentage

of reticulocytes. Folate deficiency is prevented easily by daily folic acid supplement. Exchange blood transfusions are seldom indicated for uncomplicated anemia because of the association with side effects such as alloimmunization, but can be effective for life-threatening vaso-occlusive crises (cerebral) or in preparation for surgery. As with  $\beta$ -thalassemia, sickle-cell patients on long-term transfusion programmes require iron chelation therapy to prevent iron overload. Crises should be managed with vigorous hydration because of the patient's inability to concentrate urine and the increased blood viscosity. Acidosis and hypoxia should be treated, and analgesics should be given for the accompanying severe pain.

Although hypertransfusion of packed red cells and drugs such as hydroxyurea may ameliorate the symptoms of sickle-cell disease, only bone marrow transplantation is truly curative at the present time. Bone marrow transplantation has been successfully applied to treat sickle-cell disease in children and is increasingly being used for patients with less severe, but symptomatic, diseases. Cord blood transplantation has been performed successfully when an HLA-matched sibling without sickle-cell anemia has been born. However, bone marrow transplantation is less suitable for adults who already have irreversible organ damage, and important barriers to more widespread use of bone marrow transplantation remain. These include limited availability of HLA-matched related donors, a short-term mortality of about 10% from the transplant procedure, and uncertainty as to which individuals will have severe symptomatic disease warranting such an intervention.

The concept of gene therapy in the sickle-cell syndromes holds promise for a curative approach in the future, although progress has been slow and frustrating, because of inadequate gene transfer and efficacy, and low gene expression (10). The development of a transgenic knock-out mouse model of sickle-cell disease, which undergoes sickling with deoxygenation, has provided an important animal model to study both therapeutic interventions and gene therapy manipulations to transfer globin genes or activate the endogenous  $\gamma$ -globin genes. The mouse sickle model has been corrected using a lentiviral vector to insert LCR and  $\gamma$ -globin gene sequences into the murine hematopoietic cells (11), but there remains some concerns about insertional mutagenesis using this approach. Interest has now switched to the technique of gene replacement therapy, using a protocol to replace the sickle globin gene with a normal copy of the  $\beta$ -globin gene by homologous recombination (12).

### 71.5.6 Prevention

During genetic counseling, AS $\times$ AS couples are advised of their 25% risk for having children with sickle-cell disease and certain couples may request prenatal diagnosis. However, the utilization of prenatal diagnosis for sickle-cell disease appears to be very low compared with that

for  $\beta$ -thalassemia because of the variable clinical course of the disease. An audit of more than 20 years experience of prenatal diagnosis for the hemoglobin disorders in the United Kingdom showed that only 13% of all couples at risk of having a child with sickle-cell disease underwent prenatal diagnosis.

The first method of prenatal diagnosis to be developed used fetal blood obtained by fetoscopy or placental aspiration, and the types of  $\beta$ -chains produced in fetal red cells were detected by biosynthetic studies. The significant risk of fetoscopy (6% fetal mortality), its limited availability, and the variable clinical course of the disease combined to limit the widespread use of these methods until methods involving mutation analysis of fetal DNA from amniotic fluid cells were developed in 1978. The sickle-cell gene was first detected by linkage analysis of a Hpa I restriction enzyme site, but this was quickly replaced by the direct method of restriction enzyme analysis using Mst II or Dde I, which cut the normal  $\beta^A$ -globin gene at codons 5–7 but fail to cut the  $\beta^S$ -globin gene. In 1982, the switch to using DNA from chorionic villi for prenatal diagnosis permitted prenatal diagnosis to be accomplished in the first trimester of pregnancy, although the Southern blotting technique took 5–10 days for a diagnosis to be made; the discovery and application of the PCR technique shortened the time for a diagnosis to potentially just a few hours. The application of PCR has permitted a wide variety of different methods of mutation analysis to be developed for diagnosing the sickle-cell gene, including allele-specific oligonucleotide (ASO) hybridization (known as dot blotting), reverse dot blotting, amplification specific refractory mutation system (ARMS), allele-specific priming, and oligonucleotide ligation (13). However, the simplest PCR-based method of detection, the use of Dde I to cut amplified DNA is still the most widely used approach.

### 71.5.7 Interactions with Sickle Hemoglobin

Sickle-cell disease comprises a number of compound heterozygous genotypes. Genotypes that are frequently encountered are Hb S/ $\beta$ -thalassemia or Hb S/ $\delta\beta$ -thalassemia, Hb S/C, Hb S/D-Punjab, and Hb S/O-Arab. There are also some rare interactions that have been reported in just a few families: Hb S/C-Harlem, Hb S/S-Antilles, Hb S/S-Oman, and the compound heterozygosity for Hb S and some unstable  $\beta$ -chain variants.

**71.5.7.1 Hb S/ $\beta$ -Thalassemia.** The interactions of the different types of  $\beta$ -thalassemia alleles ( $\beta^+$ ,  $\beta^0$ , and  $\delta\beta^0$ ) are described later in this chapter in the thalassemia section.

**71.5.7.2 Hb S/C Disease.** Hb C is found at frequencies of up to 0.15% in parts of West Africa, where it coexists with Hb S. Accordingly, Hb C trait occurs in about 3% of American blacks at birth, Hb SC disease in 1 in 833, and Hb C disease in about 1 in 1250. The Hb C mutation,  $\beta_6$  Glu→Lys, GAG→AAG, causes a decrease in solubility of

both the oxygenated and the deoxygenated forms of the hemoglobin, resulting in the formation of crystals instead of long polymers. In individuals homozygous for Hb C, the red cells become dehydrated and rigid, causing hemolytic anemia but such patients do not develop any sickling symptoms. The clinical importance of Hb C lies in its interaction with Hb S. The inheritance of the Hb C trait with the Hb S trait results in Hb SC disease, a milder version of sickle-cell disease. Patients with SC disease tend to have a variable course, with most complications occurring less frequently than in SS disease.

**71.5.7.3 Hb S/D Disease.** Hb S/Hb D-Punjab ( $\beta_{121}$ , Glu→Gln) results in a moderately severe form of sickle-cell disease. This compound heterozygous state has been observed in patients of African origin and from Central and South America and India, and in individuals with only Mediterranean or northern European ancestry. Patients have a mild to moderate hemolytic anemia (Hb of 5–10 g/dl) with sickling crises.

**71.5.7.4 Hb S/Hb O-Arab Disease.** Hb S/Hb O-Arab ( $\beta_{121}$ , Glu→Lys) results in a severe type of sickle-cell disorder. Hb S/Hb O-Arab patients have been observed in Arabs, Africans, Afro-Caribbeans, and Afro-Americans. The Hb concentration varies between 6 and 10 g/dl and the blood film is similar to sickle-cell anemia.

**71.5.7.5 Other Rare Sickle-Cell Disease Genotypes.** Hb S/C-Harlem ( $\beta_6$  Glu→Val and  $\beta_{73}$  Asp→Asn) is a severe sickle-cell disorder. Hb C-Harlem has two amino acid substitutions, the sickle cell substitution at codon 6, and one at codon 73 that makes the hemoglobin move like Hb C in electrophoresis at alkaline pH (7). In combination with Hb S it causes severe sickle-cell disease.

Hb S-Antilles ( $\beta_6$  Glu→Val and  $\beta_{23}$  Val→Ile) has two amino acid substitutions, similar to Hb C Harlem. It is more prone to sickling than Hb S itself and in the heterozygous state it results in a mild anemia and a moderate sickling disorder. In combination with Hb S, it is reported to produce a very severe form of sickle-cell disease with a severe chronic hemolytic anemia. Compound heterozygosity for Hb C and Hb S-Antilles also produces a severe sickle-cell disorder.

Hb S-Oman ( $\beta_6$  Glu→Val and  $\beta_{121}$  Glu→Lys) has two different phenotypes in the heterozygous state, depending on whether the patients have co-inherited heterozygous or homozygous for  $\alpha$ -thalassemia (all patients described with Hb S-Oman have  $\alpha$ -thalassemia). Patients with  $\alpha^+$ -thalassemia trait have about 20% Hb S and a moderate sickling disorder. The blood film shows a unique form of an irreversibly sickled cell called a “Napoleon Hat cell” or “yarn and knitting needle cell.” In contrast, patients with Hb S-Oman trait and homozygous  $\alpha^+$ -thalassemia have about 14% Hb S-Oman and are asymptomatic. The compound heterozygous state for Hb S and Hb S-Oman has been described in a few Omani patients. Patients have 25% Hb S and 11% Hb S-Oman, and the blood film shows Napoleon Hat cells. Patients have very severe disease, with a Hb level of 7 g/dl.

The interaction of Hb S with unstable  $\beta$ -variants may result in a mild form of sickle-cell disease. Three such variants have been described, namely, Hb Quebec-Chori, Hb Hofu, and Hb I-Toulouse. Hb S in combination with mildly unstable  $\beta$ -variants such as Hb Hope and Hb Siiraj can cause mild hemolysis.

## 71.6 UNSTABLE HEMOGLOBIN VARIANTS

### 71.6.1 Molecular Basis

At least 300 unstable hemoglobin variants are known see (Table 71-4). Among these,  $\beta$ -variants are two times more frequent than  $\alpha$ -variants, a discrepancy that may be due to the smaller percentage of unstable hemoglobin and hence milder clinical symptoms associated with the  $\alpha$ -chain variants. An individual with a single variant  $\alpha$ -gene has three normal  $\alpha$ -genes, so that the percentage of unstable hemoglobin in the red cells is very small (5–20%). In contrast, an individual with a variant  $\beta$ -gene has only a single normal  $\beta$ -gene; so the unstable hemoglobin containing the variant  $\beta$ -chain makes up a greater proportion of the total cellular hemoglobin synthesized (20–40%). Because the gene frequencies for these variants are extremely low, almost all affected individuals seen are heterozygotes.

The increased propensity of unstable hemoglobins to denature can result from several types of mutations. As mentioned previously, the  $\alpha$ -helix of  $\alpha$  or  $\beta$ -globin can be disrupted by proline replacing another amino acid within the helix. There are at least 10 examples of this type of disruption of primary and secondary structures, including Hb Bibba ( $\alpha 136$  Leu→Pro) and Hb Genova ( $\beta 28$  Leu→Pro). Deletions of amino acid residues alter primary and secondary structures as well as the conformation of the hemoglobin molecules, and 8 of the 10 variants of this type are unstable, for example, Hb Leiden ( $\beta 6$  or  $7$  Glu→0) and Hb Gun Hill ( $\beta 91$ – $95$  (Leu-His-Cys-Asp-Lys)→0). Interference with interchain contacts permits the dimers to dissociate into monomers, for example, Hb Philly ( $\beta 35$  Tyr→Phe) and Hb Tacoma ( $\beta 30$  Arg→Ser) lack hydrogen bonds normally linking the  $\alpha$  and  $\beta$  subunits. Substitutions that affect heme binding or disturb the hydrophobic heme pocket (certain nonpolar residues in the CD, E, F, and FG regions) decrease the molecule's stability see (Figure 71-1). There are over 30 such mutations, and most result in unstable hemoglobins, such as Hb Bristol ( $\beta 67$  Val→Asp) and Hb Köln ( $\beta 98$  Val→Mer). Finally, globin chain elongation can result in instability due to hydrophobic properties of the extended chain, for example, Hb Cranston ( $\beta 144$ – $151$ ).

These variant hemoglobins tend to denature spontaneously; the globin subunits precipitate in the red cell, forming aggregates or Heinz bodies. The Heinz bodies adhere to the red cell membrane and result in decreased pliability of the cell. Inflexible erythrocytes are then selectively trapped by the reticuloendothelial system.

### 71.6.2 Clinical Aspects of Unstable Hemoglobins

Patients often present in infancy or early childhood with a hemolytic anemia, jaundice, and splenomegaly, or later with cholelithiasis. Some variants also cause cyanosis because of their abnormal properties, that is, propensity to form methemoglobin or decreased oxygen affinity. Clinical severity varies with different unstable variants; for  $\beta$ -variants, symptoms appear after the  $\gamma$  to  $\beta$  transition in hemoglobin synthesis see (Figure 71-5). A number of Hb variants are associated with a thalassemic condition rather than a severe hemolytic anemia. These variants, such as Hb Agrinio,  $\alpha 29$  Leu→Pro, and Hb Quon Sze,  $\alpha 125$  Leu→Pro, are so unstable that their presence is difficult to detect except by DNA sequence analysis of the appropriate gene.

### 71.6.3 Diagnosis

The peripheral smear may be normal or hypochromic. Staining with a supravital stain, such as 1% methyl violet, demonstrates preformed Heinz bodies (Figure 71-8B). Heat instability of the variant hemoglobin is demonstrated by the formation of a hemoglobin precipitate when a hemolysate is incubated at 50 °C or higher, or at 37 °C in 17% isopropanol. Hemoglobin electrophoresis by usual methods may detect only about half of unstable variants since the charge of these variants is often unaltered by the substitutions. Oxygen saturation curves of whole blood may indicate normal (20% of the unstable variants), decreased (30%), or increased (50%) oxygen affinity.

### 71.6.4 Treatment

Treatment is generally supportive. If hemolysis is severe, prophylactic folate may be indicated. Oxidant drugs, such as sulfonamides, increase hemolysis in some patients and should be avoided. Transfusions are indicated only in the treatment of aplastic crises. While splenectomy may result in improvement of the anemia, it also increases the risk of septicemia, especially in young patients. Because of the mortality associated with septicemia in splenectomized patients, the physician should reserve splenectomy for selected patients. Splenectomy should be postponed until the patient is at least 6 years of age, and the administration of pneumococcal vaccine and prophylactic antibiotics should be considered.

## 71.7 HEMOGLOBIN VARIANTS WITH ALTERED OXYGEN AFFINITY

### 71.7.1 Molecular Basis

The oxygen dissociation curve shown in Figure 71-2 is sigmoid shaped because of heme–heme interactions. Mutations that affect the heme–heme interaction, the Bohr effect, or the deoxyhemoglobin-2,3-DPG interaction can

**FIGURE 71-8** Peripheral blood smears from patients with various disorders of globin synthesis. (A) Homozygous sickle cell anemia. (B) Unstable Hb Zurich with Heinz bodies. (C) Hb H disease. (D) Sickle/ $\beta$ -thalassemia. (E)  $\beta$ -thalassemia trait. (F) Homozygous  $\beta$ -thalassemia. Figures B and C were prepared as follows: whole blood with EDTA was incubated at 41 °C for 3–6 hours, then a 1:1 mixture of blood and 0.5% rhodanile blue in 0.9% saline was made and immediately smeared. Hemoglobin precipitates formed secondary to heating are seen. (Courtesy of Dr William Zinkham.)

change the shape or position of the oxygen dissociation curve. Mutations affecting the  $\alpha_1\beta_2$  subunit contact point can alter heme–heme interaction by causing the deoxyhemoglobin conformation to be less stable. These mutations result in increased stability of the oxyhemoglobin conformation and increased oxygen affinity (e.g. Hb Kempsey ( $\beta 99 \text{ Asp} \rightarrow \text{Asn}$ )). Alternatively, the oxyhemoglobin conformation can be destabilized by mutations affecting the  $\alpha 94\beta 102$  contact point, resulting in decreased oxygen affinity (e.g. Hb Kansas ( $\beta 102 \text{ Asn} \rightarrow \text{Thr}$ )). Substitutions at the COOH-terminal ends of globin chains can lead to instability of deoxyhemoglobin conformations

and increased oxygen affinity (e.g. Hb Bethesda ( $\beta 145 \text{ Tyr} \rightarrow \text{His}$ )) as well as a reduction in the Bohr effect. 2,3-DPG binds to residues  $\beta 1$ , 2, 82, and 143 in the deoxygenated form. Substitutions altering these residues tend to have increased oxygen affinity (e.g. Hb F ( $\gamma$ -globin has a serine for histidine substitution at position 143)).

Variants with increased oxygen affinity cause a shift to the left of the oxygen dissociation curve see (Figure 71-2), resulting in less oxygen delivery per gram of hemoglobin. To compensate, hemoglobin concentration and/or blood flow increases to partially restore oxygen delivery to the

tissues. Some variants with increased oxygen affinity do not cause polycythemia because of the small fraction of the total hemoglobin they comprise, or the compensatory changes in the shape of the oxygen dissociation curve. Variants with decreased oxygen affinity have a shift to the right and increased oxygen delivery per gram of hemoglobin. As a result, the hemoglobin concentration is normal or decreased (e.g. Hb Beth Israel ( $\beta 102 \text{ Asn} \rightarrow \text{Ser}$ )).

### 71.7.2 Clinical Aspects and Diagnosis

Because the gene frequencies for nearly all variants of hemoglobins are very low, patients are nearly always heterozygotes. The great majority of patients are asymptomatic, and when oxygen affinity is increased the major finding is polycythemia with erythrocytosis, normal white blood cell and platelet counts, and absence of splenomegaly. Since about half of these variants cannot be detected on routine electrophoresis, whole blood oxygen affinity studies are required for diagnosis. Some concern has been raised regarding the risk to fetuses of mothers who have variants with increased oxygen affinity. The few data available regarding the outcome of such pregnancies do not in general seem to indicate increased fetal mortality.

### 71.7.3 Treatment

The condition is generally considered benign. It is important to avoid chemical treatment of the compensatory polycythemia unless hematocrit levels are high enough to cause increased viscosity.

## 71.8 M HEMOGLOBIN VARIANTS

### 71.8.1 Molecular Basis

There are five known variants (with 22 different names) of M hemoglobin involving  $\alpha$ - or  $\beta$ -chains. Four of these variants result from the substitution of tyrosine for histidine at positions  $\alpha 58$ ,  $\alpha 87$ ,  $\beta 63$ , and  $\beta 92$ : Hb M-Boston ( $\alpha 58 \text{ His} \rightarrow \text{Tyr}$ ), M-Iwate ( $\alpha 87 \text{ His} \rightarrow \text{Tyr}$ ), M-Saskatoon ( $\beta 63 \text{ His} \rightarrow \text{Tyr}$ ), and M-Hyde Park ( $\beta 92 \text{ His} \rightarrow \text{Tyr}$ ). The substituted tyrosine may form a stable bond with the ferric form of the heme iron. This bond prevents interaction of the ferric iron of the affected  $\alpha$ - or  $\beta$ -chain with oxygen, but it does not render the globin-heme unit unstable. Both the  $\alpha$ -variants (M-Boston and M-Iwate) have decreased oxygen affinity, two of the  $\beta$ -variants (M-Hyde Park and M-Saskatoon) have normal affinity, and the fifth Hb M variant, M-Milwaukee-I, ( $\beta 67 \text{ Val} \rightarrow \text{Glu}$ ) has decreased oxygen affinity. Two  $\gamma$ -chain Hb M variants have been described, Hb FM-Osaka ( $\gamma 63 \text{ His} \rightarrow \text{Tyr}$ ) and Hb FM-Fort Ripley ( $\gamma 92 \text{ His} \rightarrow \text{Tyr}$ ).

### 71.8.2 Clinical Aspects

M hemoglobin variants, like other rare hemoglobin disorders, are inherited in an autosomal dominant pattern.

The age of onset of cyanosis differs depending on whether the  $\alpha$ - or  $\beta$ -chain is affected. With  $\alpha$ -chain variants, cyanosis is seen at birth;  $\beta$ -globin variants develop cyanosis when  $\gamma$  to  $\beta$  switching is nearly complete, at about 6 months of age see (Figure 71-5).

Hb FM-Osaka and Hb FM-Fort Ripley were discovered in cyanotic newborns. The babies became normal as Hb F disappeared after birth.

### 71.8.3 Diagnosis

The blood is chocolate brown and does not change color on exposure to oxygen. Usually there is no anemia, and routine electrophoresis may be normal. Spectral analysis allows differentiation of M hemoglobins from methemoglobin secondary to diaphorase I deficiency. The latter is a red cell enzyme deficiency, which is inherited as an autosomal recessive. Because the modes of inheritance for M hemoglobins and diaphorase deficiency differ, usually one parent of a patient with the former is affected, while both parents of a patient with the latter disorder are unaffected.

### 71.8.4 Treatment

No treatment is indicated; however, the diagnosis should be made so that extensive cardiac and pulmonary evaluations can be avoided.

## 71.9 THALASSEMIAS

### 71.9.1 Quantitative Disorders of Globin Synthesis

The thalassemia syndromes are defined as a group of inherited disorders characterized by the absence or reduced synthesis of one or more of the normal globin chains of hemoglobin. They are subclassified according to the particular globin genes affected and also according to the effect on gene expression. For example, the  $\beta$ -thalassemias are disorders of  $\beta$ -globin gene expression, whereas the  $\delta\beta$ -thalassemias are disorders of both  $\delta$ - and  $\beta$ -gene expression. Absent globin synthesis is designated with an “o” superscript, for example,  $\beta^0$ -thalassemia, while the presence of some normal but insufficient gene product is noted by a “+” superscript, for example,  $\beta^+$ -thalassemia. The lack of synthesis of the affected globin chain results in an unbalanced  $\alpha/\beta$  globin chain ratio and therefore the defect is a quantitative one. This is in contrast with the hemoglobinopathies in which the variant hemoglobins are qualitatively or structurally abnormal.

### 71.9.2 Geographical Basis

Thalassemia is distributed primarily among people of Mediterranean, African, Middle Eastern, Asian Indian, Chinese, and Southeast Asian descent, but sporadic cases

have been reported in many ethnic groups. The thalassemias are most common in the Mediterranean region, Africa, and Asia, but have now become a global problem through migration of populations throughout Europe, the Americas, and Australia. The high carrier rates observed in many populations are thought to have resulted from a positive selection pressure due to *Falciparum* malaria. The mechanism by which the thalassemia trait provides protection against malaria is less clear than that with the sickle-cell trait, but there is a strong geographic correlation of gene frequencies with the incidence of malaria.

The thalassemias and the Hb variants are regionally specific, with each local population having its own characteristic spectrum of mutations. For most of these populations the range of mutations has been identified by molecular analysis and the frequency of each mutation relative to the others has been determined. This information is the first step required for the control of the thalassemias through an integrated program of carrier screening, genetic counseling, and prenatal diagnosis.

### 71.9.3 Molecular Basis of $\alpha$ -Thalassemia

Both the  $\alpha$ - and the  $\beta$ -thalassemia syndromes provide examples of defects at essentially all different steps of globin chain biosynthesis.  $\alpha$ -Thalassemia is characterized by a deficiency of  $\alpha$ -globin chain synthesis and defective gene expression may occur in either one globin gene (called  $\alpha$ -2 or  $\alpha^+$ -thalassemia) or in both (called  $\alpha$ -1 or  $\alpha^0$ -thalassemia). Most of the common  $\alpha$ -thalassemia alleles result from the deletion of gene sequences in the  $\alpha$ -globin gene cluster, as depicted in Figure 71-9. An updated listing of all  $\alpha$ -thalassemia alleles is available on the Internet through the HbVar globin gene server Web site (4) (<http://globin.cse.psu.edu>).

**71.9.3.1  $\alpha^+$ -Thalassemia.**  $\alpha^+$ -Thalassemia is most commonly caused by the deletion of one of the two  $\alpha$ -globin genes. Although five different deletions have been identified, only two are commonly encountered in practice. These are the 3.7 kb deletion ( $-\alpha^{3.7}$ ), which has reached high frequencies in the populations of Africa, the Mediterranean area, the Middle East, the Indian subcontinent and Melanesia, and the 4.2 kb deletion ( $-\alpha^{4.2}$ ), which is commonly found in Southeast Asian and Pacific populations. These deletions were created by unequal crossing over between homologous sequences in the  $\alpha$ -globin gene cluster, resulting in one chromosome with only one  $\alpha$ -gene ( $-\alpha$ ) and the other chromosome with three  $\alpha$ -genes ( $\alpha\alpha\alpha$ ). Further recombination events between the resulting chromosomes have given rise to a very rare quadruplicated  $\alpha$ -gene allele ( $\alpha\alpha\alpha\alpha$ ). Individuals with five or six  $\alpha$ -globin genes are hematologically normal. However, the excess  $\alpha$ -globin chains may be sufficient to cause thalassemia intermedia when these alleles are co-inherited with the  $\beta$ -thalassemia trait.

Various nondeletion defects have also been found to cause  $\alpha^+$ -thalassemia and a total of 93 mutations have been described to date (Table 71-7), mostly in populations from the Mediterranean area, Africa, and Southeast Asia. Although nondeletion mutations are generally much less frequent than deletion mutations, among Southeast Asians, the nondeletion  $\alpha^+$ -thalassemia allele for Hb Constant Spring gene has reached a reasonably high gene frequency. This nondeletion  $\alpha^+$ -thalassemia gene encodes an abnormal  $\alpha$ -chain that has 31 additional amino acids at the COOH-terminal end and is synthesized at about 3% of the rate of normal  $\alpha$ -chains.

The different types of nondeletion mutations are similar to those described for  $\beta$ -thalassemia. There are ones that affect RNA splicing, the poly A signal and the

initiation or termination of mRNA translation; ones that cause frameshift and nonsense mutations; and ones that cause posttranslational instability. Most mutations are located in the dominant  $\alpha 2$ -globin gene and these are denoted as  $\alpha^T\alpha$  (signifying the affected gene). As there appears to be no associated compensatory change in the expression of the remaining functional  $\alpha 1$ -globin gene (as occurs with the  $-\alpha$  deletion alleles) they give rise to a slightly more severe reduction in  $\alpha$ -chain synthesis than the deletional forms of  $\alpha^+$ -thalassemia. Some have a more severe phenotype than expected, for example, the poly A (A→G) mutation and the  $-\alpha^{3.7}$  (–AC) mutation, which result in Hb H disease in the homozygous state (14), and some mutations that cause highly unstable variants that also have secondary effects on the red cell structure. The interaction of these severe nondeletional mutations with  $\alpha^0$ -thalassemia may result in a severe form of Hb H disease (15) or, very rarely, Hb Bart's hydrops fetalis syndrome in infants with a very low level of  $\alpha$ -globin chain synthesis (16).

**71.9.3.2  $\alpha^0$ -Thalassemia.**  $\alpha^0$ -Thalassemia results from deletions that involve both  $\alpha$ -globin genes in the  $\alpha$ -globin gene cluster. At least 34 different such deletions have been described. The deletions that have attained the highest gene frequencies are found in individuals from Southeast Asia and South China (–<sup>SEA</sup>), the Philippine Islands (–<sup>FIL</sup>), Thailand (–<sup>THAI</sup>), and a few Mediterranean countries such as Greece and Cyprus (–<sup>MED</sup> and  $-(\alpha)^{20.5}$ ). Although one  $\alpha^0$ -thalassemia mutation (–<sup>SA</sup>) has been described in Asian Indians it is extremely uncommon in this ethnic group. No  $\alpha^0$ -thalassemia deletions have

been reported in individuals from sub-Saharan Africa, although two very rare  $\alpha^0$ -thalassemia alleles involving the combination of the  $-\alpha^{3.7}$  deletion and a nondeletion mutation (e.g. the  $-\alpha^{3.7}$  CD 30–31 (–AG) allele) have been described. In Northern Europe  $\alpha$ -thalassemia only occurs sporadically because of the lack of natural selection, although one particular  $\alpha^0$ -thalassemia mutation (–<sup>BRIT</sup>) has been reported in a number of British families. Finally, in extremely rare instances,  $\alpha^0$ -thalassemia can also result from deletions that remove the  $\alpha$ -globin gene regulatory element about 62 kb upstream of the  $\alpha$ -globin gene complex but leave the  $\alpha$ -globin genes intact.

#### 71.9.4 Molecular Basis of $\beta$ -Thalassemia

$\beta$ -Thalassemia is caused by at least 200 different point mutations or small insertions/deletions of DNA sequence in and around the  $\beta$ -globin gene (Table 71-8), together with a much smaller number of gene deletions ranging from 25 bp to 67 kb. An updated listing of all  $\beta$ -thalassemia alleles is available on the Internet through the HbVar Web site (4). Although more than 230 different  $\beta$ -thalassemia alleles have been characterized, only approximately 30 mutations are found in at-risk groups at a frequency of 1% or greater and thus just a small number account for the majority of the mutations worldwide. All mutations are regionally specific and the spectrum of mutations has now been determined for most at-risk populations (17).

The mutations either reduce the expression of the  $\beta$ -globin gene ( $\beta^+$ -type) or result in the complete absence

of  $\beta$ -globin ( $\beta^0$ -type). A few of the  $\beta^+$ -types are associated with an unusually mild phenotype and are sometimes designated  $\beta^{++}$ -type. The mutations may affect globin gene transcription, RNA processing or translation, RNA cleavage and polyadenylation, or result in a highly unstable globin chain. Frameshift and nonsense codon mutations have been observed in all three exons and RNA processing mutations have been found in both introns and the four splice junctions. Examples of each type of mutation are shown in Figure 71-10.

**FIGURE 71-10** Diagram illustrating the  $\beta$ -globin gene and the position of thirteen examples of the different types of  $\beta$ -thalassemia mutations. Noncoding regions, hatched areas; exons, shaded areas; intervening sequences (IVS), blank areas. The types and numbers of mutations are listed below:

Type of Mutation	Total	Example	Position
Transcriptional mutations	32	-88 (C→T)	1
<b>RNA processing mutations</b>			
Splice junction changes	25	IVSI-1 (G→A)	2
Consensus site changes	19	IVSI-5 (G→C)	3
New internal splice site	8	IVSI-110 (G→A)	4
Activation of cryptic splice site in exons	5	CD 26 (G→A) (Hb E)	5
<b>RNA translation mutations</b>			
Nonsense mutations	23	CD 39 (C→T)	6
Frameshift mutations	88	CD 71/72 (+A)	7
Initiation codon mutations	8	ATG→GTG	8

Cap site mutations	1	CAP+1 (A→C)	10
5' Untranslated region mutations	7	CAP+22 (G→A)	10
Polyadenylation site mutations	10	AATAAA→AACAAA	11
3' Untranslated region mutations	3	3' UTR+6 (C→G)	12
Gene deletions (25 bp–67 kb)	20	619 bp deletion	13

**71.9.4.1 Transcription Mutations.** Transcription mutations are mostly relatively mild and are commonly observed in  $\beta$ -thalassemia intermedia. They are single nucleotide substitutions in the TATA box at -30 from the transcription start site, in the CCAAT box at -70, in the ACACCC distal promoter region at -90, and in the 5' UTR. Some, such as the mutation -101 A→C, are extremely mild ( $\beta^{++}$ -type), with carriers having borderline-reduced/normal red cell indices and normal/borderline-raised HbA<sub>2</sub> values (silent thalassemia), with homozygotes having an extremely mild form of thalassemia intermedia. Compound heterozygotes for these transcriptional mutations and the more severe  $\beta$ -thalassemia mutations tend to have a milder clinical disorder, although there are some notable exceptions. The CAP+1 A→C mutation results in a very mild disorder in the homozygous state, yet when inherited with a  $\beta^0$ -type mutation may result in thalassemia major, and the -29 A→G mutation has a mild phenotype in homozygous African individuals but is reported to result in thalassemia major in Chinese individuals homozygous for the same mutation. This ethnic difference in phenotype is partly related to different chromosomal backgrounds for this mutation, as the African mutation is linked to the C→T polymorphism at position -158 5' to the  $\gamma$ -globin gene (XmnI restriction site), which is associated with increased Hb F production under conditions of erythropoietic stress.

**71.9.4.2 RNA Splicing Mutations.** RNA splicing mutations occur at splice junctions (the invariant donor 5' GT and acceptor 3' AG dinucleotides of the introns), in consensus sequences around splice junctions, in introns to produce new donor and acceptor cryptic splice sites, and in cryptic splice sites in exons. These latter mutations alter sequences that are similar to donor splice sites at the 5' ends of introns but are not normally used for splicing. By making these sequences resemble more closely the consensus sequence for a donor splice site, these mutations activate the cryptic site, and their use leads to the production of abnormal RNA and slowed normal splicing. The second most common hemoglobin variant, Hb E, is associated with a thalassemia phenotype because the  $\beta^E$  mutation activates a cryptic splice site in exon 1, creating abnormally spliced mRNA and decreasing the formation of functional  $\beta^E$ -mRNA. Mutations that affect either of the two invariant dinucleotides of the splice junctions completely abolish normal splicing and produce the phenotype of  $\beta^0$ -thalassemia.

**71.9.4.3 RNA Modification Defects.** RNA modification defects are found at both the 5' end or cap site and the 3' end in the RNA cleavage and polyadenylation signal. The cap site mutation, which changes the first A residue to a C, may work either by reducing transcription itself or by slowing the 5' capping process that may reduce mRNA stability. The mutations in the AATAAA polyadenylation signal at the 3' end of the transcript markedly reduce RNA cleavage and lead to elongated mRNA molecules that are probably unstable. The mutations have a moderately severe  $\beta^+$ -thalassemia phenotype as only approximately 10% of the mRNA is properly

cleaved. Several  $\beta^+$ -thalassemia mutations have also been discovered in the 3' UTR. Eight mutations have been discovered that affect the initiation codon (ATG) and all produce a  $\beta^0$ -thalassemia phenotype.

**71.9.4.4 Frameshift Mutations.** Frameshift mutations are deletions or additions of 1, 2, or 4 nucleotides that change the ribosome reading frame and cause premature termination of translation at a new nonsense or chain termination codon (TAA, TAG, and TGA). Likewise, insertions, deletions, and point mutations can all generate a nonsense codon mutation, directly stopping translation. Chain termination mutations result in the majority of cases in a shortened  $\beta$ -mRNA that is often unstable and is rapidly degraded. The majority of these mutations that occur within exons 1 and 2 results in the typical recessively inherited  $\beta^0$ -thalassemia phenotype. In contrast, frameshift and nonsense mutations that occur later in the  $\beta$ -globin sequence in exon 3 often produce a clinical phenotype more severe than typical  $\beta$ -thalassemia trait and are said to be dominantly inherited.

**71.9.4.5 Missense Mutations and Dominant  $\beta$ -Thalassemia.** Missense mutations in the  $\beta$ -globin gene may produce an unstable hemoglobin variant that is associated with a  $\beta$ -thalassemia phenotype more severe than that caused by a  $\beta^0$ -thalassemia allele. These mutations, usually in the second half of exon 3, lead to a highly unstable  $\beta$ -globin chain that is rapidly degraded, so that little or no mutant hemoglobin can be detected. The unstable  $\beta$ -globin chain interacts with  $\alpha$ -globin chains before it gets degraded, forming alpha beta dimers that are also unstable and get degraded, resulting in chronic hemolytic anemia. This phenomenon makes these mutations more severe than a recessive form of  $\beta$ -thalassemia, hence the designation “dominant  $\beta$ -thalassemia.” Examples are Hb Indianapolis and Hb Showa-Yakushiji. Heterozygotes for these mutations have a moderately severe anemia with jaundice, enlargement of the spleen, gross abnormalities of the erythrocytes, and well-formed inclusion bodies in the red cell precursors.

**71.9.4.6 Deletions.** Most deletions in the  $\beta$ -globin cluster affect more than the  $\beta$ -globin gene and produce  $\delta\beta$ -thalassemia,  $\gamma\delta\beta$ -thalassemia,  $\epsilon\gamma\delta\beta$ -thalassemia, or HPFH syndromes; the majority of these different types of deletions is depicted in Figure 71-12. However, 20 different deletions have been characterized that just delete or partially delete the  $\beta$ -globin gene and result in  $\beta^0$ -thalassemia. One, the 619 bp deletion, affects the 3' end of the  $\beta$ -globin gene and is one of the most common  $\beta$ -thalassemia allele in Asian Indians. The other small deletions of the  $\beta$ -globin gene have been seen rarely. The larger deletions that delete the promoter region of the  $\beta$ -globin gene are interesting because they are associated with unusually high Hb A<sub>2</sub> levels of 6–9% in heterozygotes. The increased expression of the  $\delta$ -globin gene may be due to the fact that these deletions remove the CACCC, CCAAT, and TATA elements of the  $\beta$ -globin gene, thus eliminating competition of the b and d promoter

sequences for transacting transcription factors. Four different Hb Lepore deletions produce fusion  $\delta\beta$  globins, due to unequal crossing over between mispaired  $\delta$  and  $\beta$ -globin genes at different points between the genes, and are all associated with a  $\beta$ -thalassemia phenotype. This is in contrast to the fusion  $\gamma\beta$ -globin Hb Kenya, which behaves like an HPFH allele.

## 71.9.5 Pathophysiology

In the thalassemia syndromes, there is reduced or absent synthesis of the affected globin chain; the unaffected chain continues to be synthesized at relatively normal levels. The result is an imbalance that causes aggregation and precipitation of excess unpaired chains. In  $\beta$ -thalassemia, free  $\alpha$ -chains aggregate; the aggregates are highly insoluble and form inclusions in nucleated erythroid precursors in the bone marrow. These inclusion bodies cause intramedullary hemolysis (ineffective erythropoiesis). In contrast, in  $\alpha$ -thalassemia the  $\gamma_4$  (Hb Bart's) and  $\beta_4$  (Hb H) tetramers that form are more soluble. Thus, in severe  $\alpha$ -thalassemias, inclusions are seen in mature erythrocytes and the ineffective erythropoiesis of  $\beta$ -thalassemia is absent. In any severe thalassemia, removal of these inclusions from erythrocytes by the reticuloendothelial system damages the cells and produces “teardrop” forms. Splenomegaly can be secondary to splenic congestion or hypersplenism. After the spleen is removed, cell destruction continues at a decreased rate in the liver, and the number of red cell inclusions may increase greatly. The large number of erythroid precursors expands the marrow cavities, and bone deformities, thinning, and occasional pathologic fractures result see (Figure 71-11).

Iron accumulation results from increased gastrointestinal absorption stimulated by the anemia, blood transfusions, and decreased utilization for hemoglobin synthesis. The deposition of excess iron causes damage to the heart, pancreas, and other tissues. Chelation therapy is essential to remove excess iron stores. Folic acid requirements are increased in thalassemia. If deficiencies develop, they may worsen the anemia.

## 71.9.6 Clinical Features

The hematological characteristics of heterozygotes and homozygotes for the main types of globin gene disorders are listed in Table 71-9.

**71.9.6.1  $\alpha$ -Thalassemia.** Four clinical types are seen, depending on the number of  $\alpha$ -genes affected. In order of decreasing severity, these are Hb Bart's hydrops fetalis syndrome (all four genes affected), Hb H disease (three genes affected), heterozygous  $\alpha^0$ -thalassemia and homozygous  $\alpha^+$ -thalassemia (two genes affected), and heterozygous  $\alpha^+$ -thalassemia (one gene affected).

- Hb Bart's hydrops fetalis syndrome. This is the most severe clinical form of  $\alpha$ -thalassemia, resulting from

**FIGURE 71-11** Radiographic changes in homozygous  $\beta$ -thalassemia. (A) Thickened parietal calvaria with outer table destruction and “hair-on-end” appearance. Note absent pneumatization of maxillary sinuses and coincidental epidermoidoma. (B) Widened medullary cavities, cortical thinning, and coarse trabeculation secondary to intramedullary hyperplasia. (Courtesy of Dr John Dorst.)

homozygous  $\alpha^0$ -thalassemia (genotype:  $-/-$ ), sometimes called homozygous  $\alpha$ -thalassemia 1 or hydrops fetalis with Hb Bart's. In the usual case, over 80% of the hemoglobin in the fetal blood is Hb Bart's ( $\gamma_4$ ), which has a very high oxygen affinity, causing severe tissue hypoxia; the remainder Hb H ( $\beta_4$ ) and Hb Portland ( $\zeta_2\gamma_2$ ), the only functional Hb keeping the fetus alive. The resulting severe progressive anemia leads to massive organomegaly and heart failure. This condition is found usually in Asian infants who are spontaneously aborted or die of severe hydrops shortly after birth, although a few cases have been described in which the neonate has survived following intrauterine transfusion therapy and such patients require lifetime transfusion therapy unless they can be cured by stem cell transplantation (18). Prenatal diagnosis is always indicated because of the serious maternal complications that may occur during the pregnancy.

- Hb H disease. Hb H disease (genotypes:  $-/\alpha$ ,  $-/\alpha^T\alpha$ ) is mostly found in Southeast Asians, Greeks, and Italians. The anemia varies with an average range of 8–10 g of hemoglobin per 100 ml of blood, and reticulocytes make up 5–10% of red cells. Splenomegaly and, occasionally, hepatomegaly are found. The red cells are microcytic (decreased MCV) and their hemoglobin content is decreased [decreased mean corpuscular hemoglobin (MCH)], but the concentration of hemoglobin per cell is normal (normal MCHC). On the peripheral smear, poikilocytosis, polychromasia,

and target cells are seen. The  $\beta_4$  tetramer (Hb H) inclusions are seen easily following incubation with 1% brilliant cresyl blue, or after splenectomy they can be seen occasionally with methylene blue reticulocyte stain or Wright's stain see (Figure 71-8C). The  $\alpha/\beta$  ratio is 0.3–0.4. This imbalance causes 20% or higher levels of Hb Bart's at birth and Hb H levels of 4–30% after the switch from  $\gamma$ - to  $\beta$ -chain synthesis is complete. Both tetramers precipitate, causing inclusion body hemolytic anemia. Deficient  $\alpha$ -chain synthesis causes a drop in Hb A<sub>2</sub> ( $\alpha_2\delta_2$ ) levels to 1–1.5%. Deficient  $\alpha$ -chain synthesis is secondary to a deficiency of  $\alpha$ -globin mRNA caused by deletion of three of the four  $\alpha$ -genes. Usually, one of the parents of such a patient has  $\alpha^0$ -thalassemia trait ( $-/\alpha\alpha$ ) and the other has  $\alpha^+$ -thalassemia trait with a gene deletion ( $-/\alpha\alpha$ ) or with a nondeletion mutation ( $-/\alpha^T\alpha$ ). Hb H patients with nondeletional  $\alpha^+$ -thalassemia exhibit symptoms more severe than those with deletional  $\alpha^+$ -thalassemia, and may require recurrent blood transfusions and splenectomy. In rare cases, the interaction of  $\alpha^0$ -thalassemia with a severe type of nondeletion  $\alpha^+$ -thalassemia allele can lead to Hb H hydrops fetalis syndrome, e.g. the interaction of the  $--SEA$  allele with Hb Adana (16).

- $\alpha^0$ -Thalassemia. Heterozygous  $\alpha^0$ -thalassemia individuals (genotype:  $-/\alpha\alpha$ ) are usually of Asian or Mediterranean descent. They are relatively asymptomatic, but have a mild microcytic anemia (10–12 g of hemoglobin per 100 ml of blood) and mild poikilocytosis

**TABLE 71-9 Characteristics of the Main Types of Globin Gene Disorders**

Hematologic Features			
Disorders	Heterozygotes	Homozygous State	DNA Analysis by PCR Methods
$\alpha^+$ -Thalassemia			
Deletion ( $-\alpha$ )	0–2% Hb Bart's at birth, minimal hematologic changes	5–10% Hb Bart's at birth, low MCH and MCV	Gap-PCR: $-\alpha 3.7$ , $-\alpha 4.2$ alleles
Nondeletion ( $\alpha^T\alpha$ )	Similar to above, but hematological changes may be more severe	Hb H disease in some cases	Selective PCR of $\alpha 1$ or $\alpha 2$ , then ASO, RE-PCR or sequencing
Nondeletion ( $\alpha^{CS}\alpha$ )	0–2% Hb Bart's at birth, 0.5–1% Hb Constant Spring	Slightly more severe than heterozygous $\alpha^0$ -thalassemia	Selective PCR of $\alpha 1$ or $\alpha 2$ , then ASO, RE-PCR or sequencing
$\alpha^0$ -Thalassemia ( $-$ )	5–10% Hb Bart's at birth, low MCH and MCV; normal Hb A <sub>2</sub>	Hb Bart's hydrops fetalis; 80% Hb Bart's, 20% Hb Portland at birth	Gap-PCR: $-(\alpha)20.5$ , $--MED$ , $--SEA$ , $--THAI$ , $--FIL$ alleles; MLPA for all alleles
$\alpha^+$ -Thalassemia/ $\alpha^0$ -Thalassemia		Hb H disease; 20–40% Hb Bart's, at birth; Hb H hydrops fetalis with a few severe $\alpha^T\alpha$ alleles	As above
$\beta^0$ -Thalassemia	Low MCH and MCV; Hb A <sub>2</sub> 3.5–7.0%	Thalassemia major; Hb F 98%; Hb A <sub>2</sub> 2%	Nondeletion alleles: as for $\beta^{++}$ -thal Deletion alleles: Gap-PCR, MLPA
$\beta^+$ -Thalassemia			
Severe	Low MCH and MCV; Hb A <sub>2</sub> 4.5–7.0%	Thalassemia major; Hb F 70–95%	ASO, ARMS, sequencing
Mild	Low MCH and MCV; Hb A <sub>2</sub> 3.5–7.0%	Thalassemia intermedia; Hb F 20–40%	ASO, ARMS, sequencing
Silent	Normal MCH and MCV; Hb A <sub>2</sub> 2.8–3.8%		ASO, ARMS, sequencing
Hb Lepore	Low MCH and MCV; Hb Lepore 8–20%; low Hb A <sub>2</sub>	Thalassemia major/intermedia; Hb F 80%, Hb Lepore 20%	Gap-PCR, MLPA
$\delta\beta$ -Thalassemia	Low MCH and MCV; normal Hb A <sub>2</sub> , Hb F 4–18% (heterocellular)	Thalassemia intermedia; 100% Hb F	Gap-PCR, MLPA
HPFH			
Deletion	Normal indices; Hb F 15–35% (pancellular)	Normal; 100% Hb F	Gap-PCR, MLPA
Nondeletion	Normal indices; Hb F 1–20%	Not described	Sequencing, Xmn I for $-158 G\gamma C \rightarrow T$
Hb S	Hb A, Hb A <sub>2</sub> (3–4%), Hb S (35–40% for $\alpha\alpha/\alpha\alpha$ ; 30–35% for $-\alpha/\alpha\alpha$ ; 24–28% for $-\alpha/\alpha$ )	Hb S, Hb F (1–15%) Hb A <sub>2</sub>	RE-PCR (Dde I), ASO, ARMS
Hb S/ $\beta$ -thalassemia		$\beta^0$ : severe sickle-cell anemia; $\beta^{+}$ : less severe sickle-cell anemia $\beta^{++}$ : mild sickle-cell anemia	As above Hb S and $\beta$ -thal
Hb E/ $\beta$ -thalassemia		Thalassemia major or intermedia; 60–70% Hb E; 30–40% Hb F	ASO, ARMS, sequencing
Hb EA Bart's disease		Similar to Hb H disease; Hb E 13%, Hb A, Hb Bart's 3%	As for Hb E + $\alpha$ -thalassemia
Hb EF Bart's disease		Severe thalassemia intermedia; Hb E 80%, Hb F 15%, Hb Bart's 5%	As for Hb E + $\alpha$ -thalassemia

and anisocytosis. At birth, Hb Bart's may reach 5% in cord blood. The  $\alpha/\beta$  synthesis ratio is 0.6–0.75 (Figure 71-12). The diagnosis of  $\alpha^0$ -thalassemia trait should be considered when the MCV and MCH are low, the MCHC is relatively normal and the patient is not iron deficient, and the Hb A<sub>2</sub> is normal. This phenotype is also associated with that of homozygous  $\alpha^+$ -thalassemia (genotypes:  $-\alpha/-\alpha$ ,  $-\alpha/\alpha^T\alpha$ ,  $\alpha^T\alpha/\alpha^T\alpha$ ) and the two conditions can only be distinguished by DNA analysis techniques. Homozygous  $\alpha^+$ -thalassemia is

associated with mild elevation of Hb Bart's (>2%) in 2–5% of newborns.

- $\alpha^+$ -Thalassemia. Heterozygous  $\alpha^+$ -thalassemia (genotypes:  $-\alpha/\alpha\alpha$  or  $\alpha\alpha/\alpha^T\alpha$ ) is effectively a silent carrier state because the reduction of a mRNA is insufficient to produce significant globin chain imbalance ( $\alpha/\beta=0.8-0.9$ ) (see Figure 71-12). The hematological indices in carriers are only slightly altered and overlap considerably with those of normal individuals. A reliable diagnosis can only be made by DNA analysis.

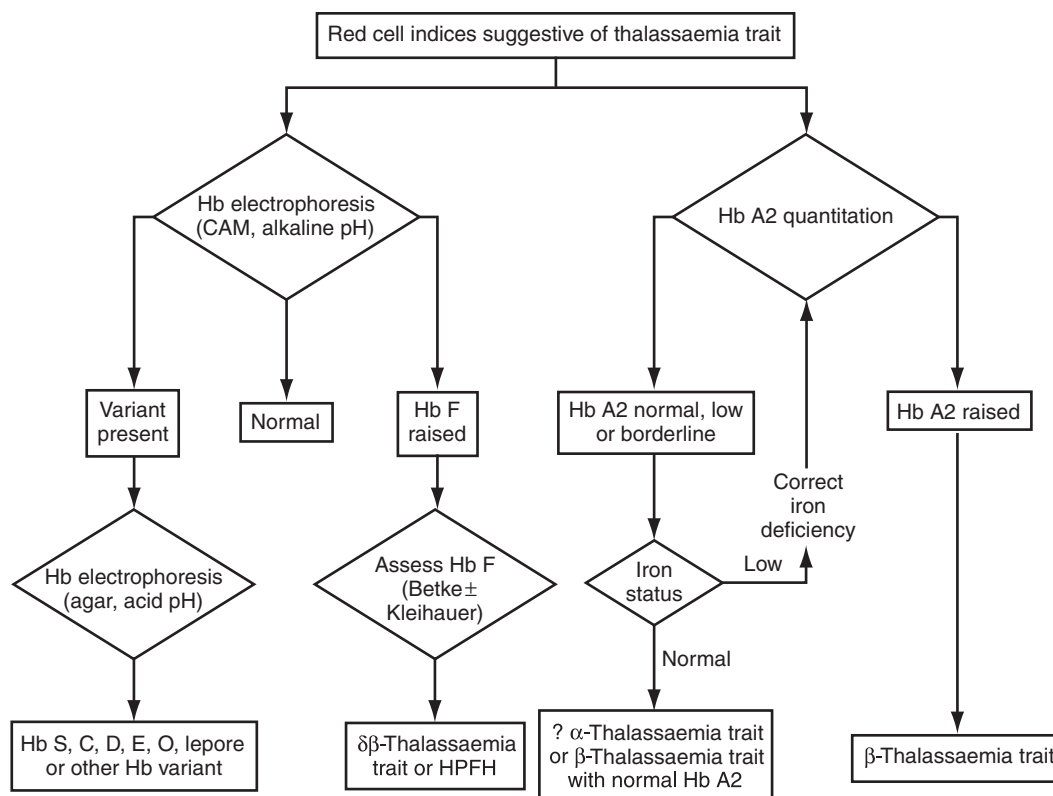

**FIGURE 71-12** Chain synthesis ratios and proposed genotypes in the different  $\alpha$ -thalassemia states.  $\alpha$ -Genes: o, normal; •, abnormal. Genotypes:  $\alpha_1$ ,  $\alpha^0$ -thalassemia;  $\alpha_2$ ,  $\alpha^+$ -thalassemia, N, normal. (Modified from Nathan, 1972, with permission.)

**71.9.6.2  $\beta$ -Thalassemia.** In contrast to the  $\alpha$ -thalassemia states in which there are four levels of severity, the  $\beta$ -thalassemias can be considered as having two degrees of severity.  $\beta$ -Thalassemia major (Cooley anemia) results from two  $\beta$ -thalassemia genes at the  $\beta$ -globin locus;  $\beta$ -thalassemia trait results from a single  $\beta$ -thalassemia gene. A milder form of homozygous  $\beta$ -thalassemia known as thalassemia intermedia also exists, the disorder resulting from a wide range of genotypes and covering a broad spectrum of phenotypes.

- $\beta$ -Thalassemia major.**  $\beta$ -Thalassemia major is a severe disease. At birth, affected infants are relatively normal because the change from  $\gamma$ -chain synthesis to  $\beta$ -chain synthesis has not been completed (see Figure 71-5). However, by 6 months of age the infant develops a severely microcytic hemolytic anemia with aniso- and poikilocytosis, polychromasia, and teardrop red cells (see Figure 71-8F). The failure in  $\beta$ -globin production due to absent or greatly decreased  $\beta$  mRNA leads to imbalance in  $\alpha$ - and  $\beta$ -globin synthesis. Subsequent precipitation of free  $\alpha$ -chains results in inclusion bodies that damage the erythrocyte membrane and lead to destruction of nucleated red cells in the marrow. The reticulocyte count is usually no greater than 5–10% because of massive destruction of erythroid precursors in the marrow. To maintain an adequate hemoglobin level, transfusions are usually required every 4–8 weeks. Affected children develop hepatosplenomegaly secondary to extramedullary hematopoiesis, and a characteristic Asian facial appearance due to excessive intramedullary hematopoiesis. The bones have expanded marrow cavities resulting in pathologic fractures and a “hair-on-end” appearance on skull films (see Figure 71-11). Other complications include cholelithiasis, susceptibility to infections, secondary

hypersplenism, and delayed growth and maturation. The major causes of mortality are hemochromatosis and overwhelming infections following splenectomy, the former due to excessive iron deposition as a result of blood transfusions and increased gastrointestinal absorption. Excess iron deposited in the heart, pancreas, liver, and other organs damages tissue and leads to cardiac failure, arrhythmias, diabetes mellitus, and liver failure. Without regular transfusion, patients usually die before the age of 20 years. Given optimal transfusion and iron chelation therapy, many patients now survive beyond the age of 40 years.

- $\beta$ -Thalassemia intermedia.** Patients with  $\beta$ -thalassemia who have a milder clinical course and are not fully transfusion dependent but have a more severe condition than the carrier states for  $\beta$ -thalassemia are classified as having  $\beta$ -thalassemia intermedia. Transfusions are not usually required in these patients even though  $\alpha/\beta$  synthesis ratios are similar to those observed in Mediterranean homozygotes. The genetic interactions leading to the phenotype of  $\beta$ -thalassemia intermedia are very heterogeneous and include homozygosity or compound heterozygosity for mild  $\beta$ -thalassemia mutations, co-inheritance of  $\alpha^0$ -thalassemia trait or homozygous  $\alpha^+$ -thalassemia and the inheritance of HPFH determinants. Inheritance of single  $\beta$ -thalassemia genes can also cause thalassemia intermedia. In the majority of cases this is related to an increased  $\alpha$ -globin production from the co-inheritance of one ( $\alpha\alpha\alpha/\alpha\alpha$ ), or in most cases, two extra  $\alpha$ -genes, either as two triplicated  $\alpha$ -genes alleles ( $\alpha\alpha\alpha/\alpha\alpha\alpha$ ), or more rarely, as a quadrupled  $\alpha$ -gene allele ( $\alpha\alpha\alpha\alpha/\alpha\alpha$ ).
- $\beta$ -Thalassemia trait.** Individuals with  $\beta$ -thalassemia trait (heterozygous  $\beta$ -thalassemia) are usually asymptomatic. The classical picture is mild anemia (10–11 g hemoglobin per 100 ml blood) with decreased MCV

**FIGURE 71-13** Approach to screening for thalassemia trait. Note that, since this approach was designed as a guide for screening of adults, other causes of microcytosis, such as lead poisoning in children, are not considered. (Modified from Pearson et al., 1973, with permission.)

(55–70) and MCH (1 pg 6–22 pg) and Hb A<sub>2</sub> raised above 3.5%. Microcytosis, anisocytosis, poikilocytosis, and targetting and stippling of the red cells can be seen on the blood smear see (Figure 71-8E). It should be noted that a small number of  $\beta$ -thalassemia heterozygotes may have normal or borderline-raised Hb A<sub>2</sub> levels. These carriers fall into two groups, those with a reduced MCV and those with a normal MCV. The first category consists of patients heterozygous for some of the mild  $\beta^+$ -thalassemia mutations, such as IVS 1-6 T→C and CAP+1 A→C, or individuals with both  $\beta$ -thalassemia and  $\delta$ -thalassemia traits. Carriers for the  $\delta\beta$ -thalassemias also have this phenotype but are distinguished by their marked increase in Hb F. The second category of atypical carriers are said to have silent  $\beta$ -thalassemia as they have normal MCV and MCH values with a borderline/normal Hb A<sub>2</sub> and normal Hb F level. They are defined by a slight imbalance in the  $\alpha/\beta$  chain ratio and are identified by DNA analysis, the mutations being designated as  $\beta^{++}$ -types. The most common silent  $\beta$ -thalassemia mutation is -101 C→T, found in Mediterranean individuals and Asian Indians (17).

### 71.9.7 Differential Diagnosis

The basic hematological tests required for carrier detection are the measurement of the MCV, the MCH value

and the quantity of Hb A<sub>2</sub> and Hb F. In addition, the hemoglobin pattern needs to be examined, and traditionally, electrophoresis methods have been used for this purpose. However, if HPLC is used to quantitate the Hb A<sub>2</sub> and Hb F level, it will also detect most of the common, clinically relevant hemoglobin variants, such as Hb S, Hb C, Hb D-Punjab, Hb O-Arab and Hb E at the same time.

In the general practice of medicine many patients present with a mild microcytic anemia. Nearly all have iron deficiency anemia or a type of thalassemia trait. In heterozygous thalassemia, the peripheral smear may be more abnormal than that of iron deficiency, and the MCV and MCH are decreased; but the MCHC is normal in contrast to the decreased MCHC seen in advanced iron deficiency anemia. The MCV in thalassemia traits also tends to be lower in relation to the red cell count than the MCV in iron deficiency. This difference is the basis of the Mentzer index (MCV/red cell count (RBC)). MCV/RBC values of less than 11.5 suggest thalassemia trait, while values greater than 13.5 suggest iron deficiency anemia. A much more definitive measurement of iron deficiency is to determine the ferritin level or to determine the erythrocyte zinc protoporphyrin (ZnPP) level. Iron deficiency is indicated by a lower-than-normal ferritin level and a higher-than-normal ZnPP value.

The first step in carrier identification is to measure the Hb A<sub>2</sub> level in patients with microcytosis (Figure 71-13).

Patients with microcytosis and normal Hb A<sub>2</sub> should have serum iron or ferritin determinations; a low value suggests iron deficiency anemia, while a normal iron or ferritin value suggests  $\alpha$ -thalassemia trait. When microcytosis and an increased Hb A<sub>2</sub> (3.5–6%) with a normal or slightly increased Hb F (2–5%) are found, a diagnosis of  $\beta$ -thalassemia trait is made. Confirmation of the diagnosis is obtained by family studies and DNA analysis. With the flowchart in [Figure 71-4](#) only the very rare cases of silent  $\beta$ -thalassemia trait,  $\beta$ -thalassemia co-inherited with  $\delta$ -thalassemia, and the extremely rare condition of  $\epsilon\delta\beta$ -thalassemia will be missed. Note that it is common for patients with a clearly raised Hb A<sub>2</sub> level to co-inherit  $\alpha$ -thalassemia, and thus antenatal patients with  $\beta$ -thalassemia trait should be screened for  $\alpha^0$ -thalassemia trait by DNA analysis when they are from Southeast Asia or Mediterranean regions where  $\alpha^0$ -thalassemia is common.

In the rare cases showing normal or low MCH and MCV values, normal or reduced Hb A<sub>2</sub> levels and a high Hb F (5–30%)  $\delta\beta$ -thalassemia trait or HPFH is indicated. These two conditions are distinguished by analyzing the Hb F distribution in the red cells and/or by DNA analysis. The  $\delta\beta$ -thalassemia trait usually has a heterogeneous distribution of Hb F (generally between 4 and 18%) while HPFH has a homogenous (pancellular) distribution (15–35%) see ([Table 71-9](#)).

### 71.9.8 Molecular Diagnosis

Mutation identification by DNA analysis techniques is required after differential diagnosis in several instances, for example, to distinguish between homozygous  $\alpha^+$ -thalassemia and  $\alpha^0$ -thalassemia trait, to distinguish between  $\delta\beta$ -thalassemia trait and HPFH with co-inherited  $\alpha$ -thalassemia, and to give a definitive diagnosis of Hb D-Punjab in antenatal patients following a presumptive diagnosis by HPLC or electrophoresis. Genotype analysis is also necessary for prenatal diagnosis by fetal DNA analysis and for solving complex difficult diagnostic cases due to the interaction of several alleles or mutations with atypical phenotypes. The major PCR-based approaches for diagnosing thalassemia mutations are summarized in [Table 71-9](#).

The technique of Gap-PCR is the most widely used method for the diagnosis of the common  $\alpha$ -thalassemia deletion alleles, and multiplex assays have been developed to identify the two most common  $\alpha^+$ -thalassemia deletion genes, the  $-\alpha^{3.7}$  and  $-\alpha^{4.2}$  alleles, and five  $\alpha^0$ -thalassemia deletion mutations, the  $_{-FIL}$ ,  $_{-THAI}$ ,  $_{-MED}$ ,  $-(\alpha)^{20.5}$  and the  $_{-SEA}$  alleles ([19](#)). The many rare  $\alpha^0$ -thalassemia deletion alleles cannot be identified by Gap-PCR because the breakpoint DNA sequences have not been characterized for primers to be synthesized; however they can be detected, although not definitively identified, by the technique known as multiplex ligation-dependent probe amplification (MLPA) ([20](#)).

The diagnosis of nondeletion  $\alpha^+$ -thalassemia mutations is more complicated than the diagnosis of  $\beta$ -thalassemia mutations as it requires specific preamplification of one of the two  $\alpha$ -globin genes before a PCR-based diagnostic can be applied. Known mutations may be diagnosed by simple quick techniques, such as restriction enzyme polymerase chain reaction (RE-PCR) for the Hb Constant Spring mutation, or by the amplification refraction mutation system (ARMS) PCR for regionally specific mutations in Southeast Asia ([21](#)). However, for unknown mutations, DNA sequencing of each  $\alpha$ -globin is the gold standard technique used by most laboratories.

For the identification of  $\beta$ -thalassemia point mutations, many different PCR-based approaches have been developed over the past 20 years, from simple methods of hybridization of labeled oligonucleotides to highly technological methods using primer extension microarrays. However, the simplicity of the mutation spectrum in countries without a large multiethnic immigrant population makes it easy to screen for most  $\beta$ -thalassemia mutations with simple cheap techniques if the ethnic origin of the patient is known. The most widely used techniques are based on the principles of ASO hybridization or allele-specific priming, such as reverse dot blotting or ARMS-PCR ([22](#)). Each population at risk has its own particular spectrum of  $\beta$ -thalassemia mutations enabling prenatal diagnosis to be carried out by screening for the common mutations in that particular ethnic group. The common mutations (at frequency of 1% or more) for the major ethnic groups (Mediterranean, Indian, Chinese, and African) are listed in [Table 71-10](#). The ARMS-PCR technique has been developed to identify all these common mutations ([23](#)). For countries with large multiethnic populations, the number of mutations required to be diagnosed is much greater and a general method for both known and unknown mutations such as DNA sequencing is more useful. Microarray technology holds the promise of being able to screen for all the 1000 thalassemia and Hb variant point mutations simultaneously, and several groups have developed arrays to screen a DNA sample for up to 23  $\beta$ -thalassemia point mutations in one analysis ([24,25](#)). Large  $\beta$ -thalassemia deletion mutations, including  $\delta\beta$ -thalassemia and HPFH deletion alleles, can be identified by gap-PCR if the deletion breakpoints have been characterized, or simply detected by MLPA if they are unknown ([26](#)).

**71.9.8.1  $\delta\beta$ -Thalassemia.** Homozygous  $\delta\beta$ -thalassemia is a mild disorder and one of the many genotypes that result in thalassemia intermedia. Homozygotes have 100% Hb F and lack Hb A and Hb A<sub>2</sub>. The mild anemia and hemolysis are due to increased  $\gamma$ -chain synthesis, which makes the imbalance between synthesis of  $\alpha$ -chains and non- $\alpha$  chains less than that seen in other  $\beta$ -thalassemias. Patients with heterozygous  $\delta\beta$ -thalassemias have mild microcytosis and 4–18% Hb F on electrophoresis see ([Table 71-9](#)). They are classified

**TABLE 71-10 The Distribution of the Common  $\beta$ -Thalassemia Mutations and Their Relative Gene Frequencies**

Mutation	Mediterranean			Indian		Chinese		African

into two groups: the  $(\delta\beta)^0$ -thalassemias in which the Hb F is composed of both  $G_\gamma$  and  $A_\gamma$  chains (13 deletion mutations), and the  $(A_\gamma\delta\beta)^0$ -thalassemias in which the Hb F contains only  $G_\gamma$  chains see (Figure 71-11) due to  $A_\gamma$ -globin gene being deleted (15 deletion mutations).

**71.9.8.2 Hb Lepore Thalassemia.** As previously mentioned, Hb Lepore is a variant hemoglobin containing a  $\delta\beta$ -fusion chain. Four different Hb Lepore variants have been described (Hollandia, Boston/Washington, Baltimore and Leiden), differing in the point at which the  $\delta\beta$ -fusion occurs. Hb Lepore has an electrophoretic mobility similar to that of Hb S, and it forms 5–15% of the total hemoglobin of heterozygotes see (Table 71-9). It can be easily identified by IEF gel electrophoresis in which it focuses to a characteristic position between Hb A and S. Decreased Hb Lepore synthesis may be secondary to instability of the  $\delta\beta$ -fusion mRNA. Heterozygotes are clinically similar to  $\beta^0$ -thalassemia heterozygotes and Hb Lepore homozygotes, or Lepore/ $\beta^0$ -thalassemia genetic compounds are similar to  $\beta^0$ -thalassemia homozygotes with a severe thalassemic picture ranging from transfusion-dependent disease to thalassemia intermedia when ameliorated by other factors such as  $\alpha$ -thalassemia.

**71.9.8.3  $\epsilon\gamma\delta\beta$ -Thalassemia.** Infants heterozygous for this rare condition are born with a severe hemolytic, hypochromic anemia and microcytosis and may require blood transfusions. The condition improves at 3–6 months after birth and adults have a phenotype similar to heterozygous  $\beta$ -thalassemia but with a normal Hb  $A_2$  level. Seventeen large deletion mutations have been described, which delete all the functional globin genes ( $\epsilon$ ,  $G_\gamma$ ,  $A_\gamma$ ,  $\delta$ , and  $\beta$ ) and three have been described in which the deletion leaves the  $\beta$ -globin gene intact but not expressed. Mapping of the deleted DNA of the latter cases shows that in all three cases the locus control region (LCR) located 5' to the  $\epsilon$ -gene has been removed. The absence of this segment inactivates all the intact globin genes following the 3' end of the deletion. The homozygous condition is presumed to be incompatible with fetal survival.

**71.9.8.4  $\delta$ -Thalassemia.** Individuals with heterozygous and homozygous  $\delta^0$ -thalassemia have, respectively, decreased and absent Hb  $A_2$ . However, anemia and changes in peripheral smears are not seen because of the normal low level of  $\delta$ -chain production see (Figure 71-5). At least 26 different  $\delta$ -thalassemia alleles have been described. Their only clinical significance is when they are co-inherited with

FIGURE 71-14 Deletion mutations in the β-globin gene cluster.

heterozygous β-thalassemia and complicate the diagnosis because of a normal Hb A<sub>2</sub> level of 2–2.5%.

**71.9.8.5 Hereditary Persistence of Fetal Hemoglobin.** HPFH is a disorder in which Hb F is increased above the normal adult level and there are no morphological

changes to the red cells. The disorder is caused by at least 25 different mutations, either large deletions in the globin gene cluster (Figure 71-14) or point mutations in the γ-gene promoter regions. HPFH heterozygotes differ from thalassemia heterozygotes in that they have no imbalance

between the synthesis of  $\alpha$  and non  $\alpha$ -chains (i.e.  $\gamma$  and  $\beta$ -chains) and thus are characterized by an asymptomatic heterozygous state without microcytosis. The elevated Hb F ranges from 3 to 35%, depending on the type of the mutation. The proportion of  $\gamma$ -chain type ( $G_\gamma$  versus  $A_\gamma$ ) varies among patients with different HPFHs and usually, but not always, the Hb F is homogeneously distributed within red cells, in contrast to db and other thalassemias. In a few cases, HPFH heterozygotes have two populations of cells: one contains Hb F; the other lacks Hb F. These patients are said to have heterocellular HPFH, as opposed to the bulk of patients who have pancellular HPFH.

There are seven types of deletional HPFH (including the deletion that gives rise to the fusion globin Hb Kenya) and at least 14 different nucleotide changes responsible for nondeletional HPFH. The  $\beta$  and  $\delta$ -genes are deleted in the deletional HPFH types, but both are present and active in the nondeletional HPFH cases. In these latter cases, point mutations between -202 and -110 upstream of the  $A_\gamma$  and  $G_\gamma$  globin genes have been found.

The differences between HPFH and  $\delta\beta$ -thalassemia are subtle, but in  $\delta\beta$ -thalassemia the clinical picture and blood smears are somewhat more abnormal and the Hb F has a more heterogeneous cellular distribution. HPFH homozygotes have mild hypochromia, microcytosis, and morphologic changes in the red cells; 100% of the hemoglobin is F, and there is no anemia. In some of these cases,  $\alpha/\gamma$  chain synthesis ratios of 1.5 occur, similar to the  $\alpha/\beta$  ratios seen in milder  $\beta$ -thalassemia trait. It has been hypothesized that a suppression region for  $\gamma$ -chain synthesis is located between the  $A_\gamma$  and  $\delta$  loci and that HPFH, but not  $\delta\beta$ -thalassemia mutations, inhibits its function. However, suppression and activation regions in the  $\beta$ -globin gene cluster appear multiple in number, and a clear picture explaining the difference between the deletions of the two disorders has not emerged.

## 71.9.9 Interaction of Thalassemia with Hemoglobin Variants

**71.9.9.1  $\alpha$ -Thalassemia/Hb Q-Thailand ( $\alpha 74$  Asp  $\rightarrow$  His).** The Hb Q-Thailand mutation is linked to  $\alpha^+$ -thalassemia allele: the mutation is located in the  $\alpha 1$ -gene on a chromosome in which the  $\alpha 2$ -gene is deleted ( $-\alpha^Q$ ). Thus, the quantity of Hb Q-Thailand in heterozygotes is 30–35%, higher than normal for an  $\alpha$ -chain variant. The genetic compound of  $\alpha^0$ -thalassemia ( $-$ ) and Hb Q-Thailand is found Thai, Chinese, and Japanese families. The clinical picture is similar to that of Hb H disease, but there is an absence of Hb A synthesis.

**71.9.9.2  $\alpha$ -Thalassemia/Hb G-Philadelphia ( $\alpha 68$  Asn  $\rightarrow$  Lys).** Hb G-Philadelphia is linked with an  $\alpha^+$ -thalassemia allele in some ethnic groups. Heterozygotes for Hb G-Philadelphia, the most common  $\alpha$ -chain variant in individuals of African origin, show a trimodal distribution of Hb G (22, 30, and 41% of the total hemoglobin). This is because the Hb G-Philadelphia mutation is

located on either a normal  $\alpha$ -gene allele ( $\alpha^G\alpha$ ) or an  $\alpha^+$ -thalassemia allele ( $-\alpha^G$ ). Individuals with 22% Hb G-Philadelphia have three normal  $\alpha$  genes in addition to one  $\alpha^G$  gene ( $\alpha\alpha/\alpha^G\alpha$ ). Those with 30% Hb G-Philadelphia have one normal  $\alpha$ -gene allele and one  $\alpha^+$ -thalassemia allele containing just a single  $\alpha$ -gene: the Hb G-Philadelphia mutation may be on the  $\alpha^+$ -thalassemia allele ( $\alpha\alpha/-\alpha^G$ ) or on the normal allele ( $-\alpha/\alpha^G\alpha$ ). Those with 41% Hb G have homozygous  $\alpha^+$ -thalassemia, with one chromosome containing a single  $\alpha^G$  gene and another with a single  $\alpha^A$  gene ( $-\alpha/-\alpha^G$ ).

**71.9.9.3  $\alpha$ -Thalassemia/Hb S.** Sickle-cell heterozygotes show a trimodal distribution of the percentage Hb S because of the effect of  $\alpha^+$ -thalassemia. AS individuals who are normal with respect to  $\alpha^+$ -thalassemia ( $\alpha\alpha/\alpha\alpha$ ) have 36–40% Hb S, those with  $\alpha^+$ -thalassemia trait ( $\alpha\alpha/-\alpha$ ) have 30–34% Hb S, and those homozygous for  $\alpha^+$ -thalassemia ( $-\alpha/-\alpha$ ) have 24–28% Hb S.

**71.9.9.4  $\alpha$ -Thalassemia/Hb E.** In Southeast Asia, Hb E heterozygotes who inherit  $\alpha$ -thalassemia also show a reduction in the percentage Hb E in a manner similar to AS individuals as described previously. AE individuals who are normal with respect to  $\alpha^+$ -thalassemia ( $\alpha\alpha/\alpha\alpha$ ) have 25–30% Hb S, those with  $\alpha^+$ -thalassemia trait ( $\alpha\alpha/-\alpha$ ) have 21–25% Hb S, and those homozygous for  $\alpha^+$ -thalassemia ( $-\alpha/-\alpha$ ) or heterozygous  $\alpha^0$ -thalassemia ( $-\alpha/\alpha$ ) have 19–21% Hb S. All these combinations are asymptomatic disorders. However,  $\alpha$ -thalassemia genotypes can interact with Hb AE and Hb EE genotypes to produce symptomatic disorders. The most commonly observed disorders are Hb AE Bart's disease and Hb EF Bart's disease (Table 71-6).

Hb AE Bart's disease results from the interaction of an Hb H disease genotype with the heterozygous state for Hb E. The disorder is characterized by the presence of Hb A, Hb E (13–15%), and Hb Bart's on hemoglobin analysis. The clinical manifestations are similar to Hb H disease, with patients having a variable degree of anemia and splenomegaly. Two common subtypes of Hb AE Bart's disease have been observed:  $\alpha^0$ -thalassemia/ $\alpha^+$ -thalassemia ( $-\alpha/-\alpha$ ) with heterozygous Hb E ( $\beta^A/\beta^E$ ) and  $\alpha^0$ -thalassemia/Hb Constant Spring ( $-\alpha^{CS}\alpha$ ) with heterozygous Hb E ( $\beta^A/\beta^E$ ). The latter disorder was found to have a more severe clinical syndrome.

Hb EF Bart's disease results from the interaction of an Hb H disease genotype with homozygous Hb E. The disorder is characterized by the presence of Hb E, Hb F, and Hb Bart's on hemoglobin analysis. Hb E constitutes approximately 80%, Hb F 10%, and Hb Bart's 10%. Patients with this condition have severe thalassemia intermedia, with a Hb level ranging from 6 to 10g/dl and markedly reduced MCV and MCH values. Four compound genotypes for Hb EF Bart's disease have been identified: (i)  $\alpha^0/\alpha^+$ -thalassemia ( $-\alpha/-\alpha$ ) plus homozygous Hb E ( $\beta^E/\beta^E$ ), (ii)  $\alpha^0$ -thalassemia/Hb Constant Spring ( $-\alpha^{CS}\alpha$ ) plus homozygous Hb E ( $\beta^E/\beta^E$ ), (iii)  $\alpha^0/\alpha^+$ -thalassemia ( $-\alpha/-\alpha$ ) plus Hb E/ $\beta^0$ -thalassemia, and (iv)  $\alpha^0$ -thalassemia/Hb

Constant Spring ( $--/\alpha^{CS}\alpha$ ) plus Hb E/ $\beta^0$ -thalassemia. To differentiate among these genotypes, family studies and further investigation by DNA analysis are required.

**71.9.9.5  $\beta$ -Thalassemia/Hb S.** Hb S/ $\beta$ -thalassemia is characterized by microcytic red and target cells with occasionally sickled forms. Hemoglobin electrophoresis reveals 60–90% Hb S, 0–30% Hb A, 1–20% Hb F, and an increased Hb A<sub>2</sub> level. The percentages of Hb S and Hb A vary depending on whether the  $\beta$ -thalassemia gene is  $\beta^+$  or  $\beta^0$  type. Coexisting  $\alpha$ -thalassemia increases the Hb concentration, the MCV, and MCH.

The clinical course of sickle-cell  $\beta$ -thalassemia is very variable, ranging from a disorder identical with sickle-cell anemia to a completely asymptomatic condition. The Hb concentration varies from 5 g/dl to a level within the normal range. The heterogeneity is mostly due to the type of  $\beta$ -thalassemia mutation that is co-inherited. It tends to be very mild in Africans because of the likelihood of the co-inheritance of one of the three mild  $\beta^+$  mutations commonly found in this racial group ( $-88, C \rightarrow T$ ;  $-29, A \rightarrow G$ ; CD24,  $T \rightarrow A$ ). However, those patients who inherit a  $\beta^0$ -thalassemia allele exhibit a clinical disorder very similar to sickle-cell anemia.

**71.9.9.6  $\beta$ -Thalassemia/Hb C.**  $\beta$ -Thalassemia/Hb C is mostly seen among individuals of African origin. The disorder is clinically heterogeneous because of the different types of  $\beta$ -thalassemia alleles involved. Hb C/ $\beta^+$ -thalassemia in Africans has hematologic features similar to those of  $\beta$ -thalassemia trait because  $\beta^+$ -thalassemia mutations are the mild types, as described previously for Hb S/ $\beta^+$ -thalassemia. However, Hb C/ $\beta^+$ -thalassemia with a severe type of mutation and Hb C/ $\beta^0$ -thalassemia produce a more severe phenotype, characterized by an anemia of 8–12 g/dl and splenomegaly. The clinical picture is a slightly more severe form of Hb C disease (homozygous Hb C), with which individuals have a mild hemolytic anemia (10–15 g/dl) and moderate splenic enlargement. Hb C is less soluble than Hb A in both the oxygenated and deoxy forms, resulting in the formation of crystals in high concentrations. Hb CC red cells become dehydrated, dense, and abnormally rigid, resulting in a shortened life span. AC individuals have no clinical manifestations and normal hematological values, although their red cells are slightly dehydrated and dense. Diagnostically, Hb C/ $\beta^0$ -thalassemia can be difficult to distinguish from Hb C disease (Hb CC) because of overlap of the hematological findings and the fact that, apart from HPLC, the commonly used methods of hemoglobin analysis do not distinguish Hb A<sub>2</sub> from Hb C. A raised Hb A<sub>2</sub> level by HPLC, family studies, or DNA analysis is required.

**71.9.9.7  $\beta$ -Thalassemia/Hb E.** Hb E/ $\beta$ -thalassemia is a common disease in Thailand and parts of Southeast Asia. It results in a variable clinical picture similar to that of homozygous  $\beta$ -thalassemia, ranging from a condition indistinguishable from thalassemia major to a mild form of thalassemia intermedia. The severest conditions are

found in individuals with Hb E and  $\beta^0$ -thalassemia, who usually have about 50–70% Hb F, the remainder being Hb E. Hemoglobin levels may be as low as 4–5 g/dl, and the clinical management of these patients is similar to that for those with thalassemia major. Compound heterozygotes for Hb E and  $\beta^+$ -thalassemia usually have a milder disorder and produce variable amounts of Hb A, with the mildest phenotype resulting from mild  $\beta^+$ -type mutations such as  $-28 (A \rightarrow G)$  and codon 19 ( $G \rightarrow A$ ), although some patients with severe  $\beta^+$ -type mutations such as IVS I-5 ( $G \rightarrow C$ ) and IVS II-654 ( $C \rightarrow T$ ) can produce symptoms as severe as Hb E/ $\beta^0$ -thalassemia (27). As with homozygous  $\beta$ -thalassemia, the genetic factors that account for a mild phenotype in some, but not all patients, are mild  $\beta^+$ -type mutations, the co-inheritance of  $\alpha$ -thalassemia, and the homozygosity for the XmnI restriction site due to the  $C \rightarrow T$  polymorphism at position  $-158 5'$  to the  $\gamma$ -globin gene.

**71.9.9.8  $\delta\beta$ -Thalassemia/Hb S.** Hb S/ $\delta\beta$ -thalassemia is a milder form of sickle-cell disease than sickle-cell anemia, because the high percentage of Hb F (15–25%) produced by the  $\delta\beta$ -thalassemia allele protects against red cell sickling by reducing the Hb S concentration and inhibiting its polymerization. Hb S/ $\delta\beta$ -thalassemia has been described in Sicilian, Italian, Greek, Arab, and African-American individuals. Patients have a mild anemia with a Hb concentration in the range of 10–12 g/dl, a significantly reduced MCH and MCV, Hb S, Hb F, and a normal or low Hb A<sub>2</sub> level.

**71.9.9.9 HPFH/Hb S.** Patients doubly heterozygous for Hb S and HPFH are either asymptomatic or have an extremely mild form of sickle-cell disease. There is usually no anemia and patients have very few episodes suggesting sickle-cell crises, although occasional mild bone pain has been reported. The condition is found in individuals of African origin (with either the black HPFH1 or Ghanaian HPFH2 deletions), and also in Asian Indians (with the Indian HPFH3 deletion). Patients have near-normal red cells with 20–30% Hb F in a pancellular distribution. The condition is difficult to distinguish diagnostically from Hb S/ $\delta\beta$ -thalassemia without DNA analysis because many patients have reduced red cell indices due to co-inherited  $\alpha^+$ -thalassemia.

## 71.9.10 Management of Thalassemia

**71.9.10.1 Prevention.** The hemoglobin disorders are the most common clinically serious single gene disorders in the world. About 250 million people are carriers and about 300,000 affected homozygotes for thalassemia and sickle-cell disease are born each year, the majority in countries with limited resources. Because the treatment for affected patients is still not perfect and very expensive, from the public health perspective the most important means of controlling thalassemia is prevention by antenatal screening and prenatal diagnosis. Most countries have implemented prevention programs,

based on the identification of couples at risk by carrier screening, the provision of information by nondirective counseling, and the option of prenatal diagnosis to allow the termination of an affected fetus if required. Such programs have been extremely successful in the populations at risk in the Mediterranean area, leading to a marked decline in the incidence of thalassemia major.

In England, the Department of Health has recently implemented the NHS Sickle Cell and Thalassemia Screening Programme in order to improve the provision of screening services. This consists of two linked screening programmes for hemoglobinopathies: sickle cell screening of all newborns and sickle cell and thalassemia screening during pregnancy. The antenatal screening program has two approaches, each with its own screening algorithm, depending on whether the local population to be covered by the screening laboratory is defined as low prevalence or high prevalence (affected births greater than 1.5 per 10,000 pregnancies). The screening program is designed to detect the main hemoglobinopathy carrier states that combine to give rise to the risk of an affected fetus:  $\alpha^0$ -thalassemia,  $\beta$ -thalassemia,  $\delta\beta$ -thalassemia, and Hb's C, D-Punjab, E, Lepore, and S (28).

From 1975 to 1980, prenatal diagnosis of various thalassemias was done exclusively by the analysis of the relative synthesis of globin chains in fetal blood. The procedure usually resulted in adequate fetal blood samples (>90%) with few technical errors. However, the method is associated with a 6% risk of fetal loss and cannot be performed until 18 weeks of gestation, which means a long wait for the mother for a result and, if indicated, a relatively difficult elective abortion. Despite the disadvantages inherent in the method, it proved very successful with over 13,000 cases being carried out in over 20 diagnostic centers worldwide (1) until molecular diagnostic techniques were introduced.

In 1978, prenatal diagnosis of sickle-cell disease by restriction endonuclease mapping of fetal DNA from amniotic fluid cells was shown to be possible, quickly followed by the application of the same approach to  $\beta$ -thalassemia, although this was still a second-trimester procedure. However, in 1982, the first case of a first-trimester fetal diagnosis using chorionic villus DNA was achieved and this approach quickly became the method of choice for prenatal diagnosis worldwide. Chorionic villi were a better source of fetal DNA than amniocytes and the first-trimester diagnosis enables an easier therapeutic termination if required. The application of PCR methods decreased diagnostic turn around times dramatically and also increased the accuracy of the diagnosis. Commonly used diagnostic techniques for prenatal diagnosis include ASO hybridization with dot blots or reverse dot blots, restriction enzyme digestion of amplified product, allele-specific priming techniques, denaturing gradient gel electrophoresis, gap-PCR, and direct nucleotide sequencing of amplified globin gene product (29). For the future, microarray technology offers the

most potential for the mass screening of mutations combined with automation, but may not find many applications for prenatal diagnosis because of the relatively high costs of this technology (30).

Recent developments in prenatal diagnosis have been directed toward noninvasive methods of fetal sampling and preimplantation diagnosis (PGD). The use of fetal nucleated red blood cells that circulate in the blood of pregnant women was the first approach to be explored. Prenatal diagnosis of sickle-cell disease and  $\beta$ -thalassemia was achieved in 1986 by the analysis of DNA from single cells after enrichment and positive identification for removal from a slide by microdissection. However, this approach has not been repeated with great success and remains technically very difficult (31). Current research is targeting better specific fetal cell markers and other ways of isolating single fetal cells, such as noncontact laser capture microdissection. One successful application of this technique has been the prenatal detection of Hb Bart's hydrops fetalis syndrome by antibody staining of fetal erythrocytes in maternal blood for  $\alpha$ - and  $\zeta$ -globins, as these cells from an affected fetus cannot express  $\alpha$ -globin (32).

The discovery of fetal DNA in maternal plasma offers a much simpler and more robust approach to noninvasive prenatal diagnosis, as the DNA is cleared very rapidly from the maternal plasma post partum and enrichment steps are desirable but not absolutely required (33). The use of this DNA poses a significant technical challenge, as the cell-free DNA is very fragmented (less than 300 bp in size) and is present in much lower amounts compared to the maternal cell free DNA and therefore highly sensitive detection methods are required. The technique is being used for the prenatal diagnosis of sex-linked diseases and for determining the fetal RhD blood group type (34). However, for the hemoglobinopathies the rate of progress has been much slower, and for several years the technique was only applied for prenatal diagnosis of the thalassemias (and other recessive disorders) by the exclusion of the paternally derived allele (35). The use of linked markers offers the potential to diagnose both maternal and paternal alleles, but probably the most exciting development with this approach is the application of the new technologies of digital PCR and next-generation sequencing techniques for prenatal diagnosis by measuring the balance of the mutant and normal alleles (36).

PGD for  $\beta$ -thalassemia is now offered by a growing number of diagnostic centers around the world. The technique represents a "state-of-the-art" procedure that potentially avoids the need to terminate affected pregnancies. The approach is especially useful for couples who have already had one or more elective terminations, and also for couples for whom religious or ethical beliefs will not permit the termination of pregnancy. The two main approaches are by polar body DNA analysis and by the analysis of DNA from a blastomere

biopsy from a cleavage stage embryo (37). The PCR techniques must be able to diagnose the required genotype in single cells reliably and accurately, in order to avoid the problem of allele drop out, which could lead to a misdiagnosis. PGD is a technically challenging, multistep, and expensive procedure, with a low overall success rate and is not likely to become a routine alternative to conventional prenatal diagnosis for couples in most countries. However, a small number of centers around the world are now set up to carry out this procedure and PGD has been used successfully for both  $\alpha$ -thalassemia (38) and  $\beta$ -thalassemia (39). One specific use of this approach is to allow the birth of a normal child that is HLA identical to a sibling affected with  $\beta$ -thalassemia, thus permitting a possible cure by stem cell transplantation (40).

**71.9.10.2 Therapy.** Advances in the management of thalassemia major have greatly improved the prognosis for patients with this disease, although its management remains complex, difficult, and very expensive. Regular transfusion and optimum iron chelation therapy enables patients to survive at least to the third decade with a normal lifestyle in countries able to afford the treatment program, and survival to the fourth decade is now common. However, in the third world countries where thalassemia reaches its highest frequency, widespread adoption of this expensive treatment is not possible and the problem of thalassemia remains almost untouched. Revised guidelines for the clinical management of thalassemia have recently been published and can be downloaded from the Thalassemia International Federation Web site ([www.thalassemia.org.cy](http://www.thalassemia.org.cy)) (41).

**Anemia.** Treatment for severe  $\beta$ -thalassemia is primarily symptomatic. If anemia is severe enough, transfusions are required to maintain adequate levels of hemoglobin. Thalassemia major children require regular transfusions to maintain the pretransfusion hemoglobin at a target between 9.0 and 10.5 g per 100 ml. This approach may require 2–3 units every 2–4 weeks in adults. If started early in life this hypertransfusion regimen prevents all the bone malformations and abnormalities characteristic of untransfused thalassemia major children. Patients are transfused with washed or frozen red cells uncontaminated by white cells and plasma proteins to avoid the development of severe reactions to transfusion caused by leukocyte sensitization.

**Iron Accumulation.** Hypertransfusion is associated with substantial iron loading. Chronic iron overload can cause cardiac, liver, and endocrine problems, and eventually death. Iron chelation therapy is used to prevent this side effect of chronic transfusion. Transfused patients who do not receive or do not accept chelation therapy accumulate in excess of 70 g of iron by the second decade of life. This is almost a lethal dose and cardiac failure due to cardiac hemosiderosis remains the leading cause of death in thalassemia patients. The first drug available for treatment of iron overload was

desferrioxamine (Desferal). This drug is not orally absorbed and is injected subcutaneously into the abdominal wall by overnight infusion by a pump; this treatment is cumbersome and cannot be tolerated by many patients, resulting in poor compliance. It is an extremely costly regimen and completely beyond the means of less developed countries.

The cost, inconvenience, and difficulty of desferrioxamine therapy have driven the search for cheaper orally administered iron chelating drugs. A number of potential oral iron chelators have been identified but only two, the hydroxypyridone compound known as L1 or deferiprone and the tridentate bis-hydroxyphenyl-tiazole compound known as Deferasirox (ICL670, Exjade), are now in widespread clinical use following extensive clinical trials. These studies have shown that deferiprone is about 70% effective as desferrioxamine at iron excretion and results in a decrease of serum ferritin levels, although a number of treatable side effects have been observed, including nausea, agranulocytosis, and neutropenia (42). Deferiprone is not as effective in controlling hepatic iron concentration but is more effective than desferrioxamine in the removal of myocardial iron (43) and treatment is associated with reduced cardiac morbidity (44). Deferiprone has been licensed for use in 25 countries as a cheap, orally active alternative to desferrioxamine, but is not licensed in North America.

Desferrioxamine and deferiprone can be used in combination therapy to achieve levels of iron excretion that cannot be achieved by either drug alone. Combination therapy decreases the number of desferrioxamine infusion days, thus improving compliance and quality of life and appears to be effective, well tolerated, and acceptable to patients (45). Trials evaluating combined therapy versus desferrioxamine monotherapy have shown a significant improvement in myocardial T2\* levels and combination therapy should be considered for patients who comply poorly with desferrioxamine monotherapy or high-risk cases with particularly low myocardial T2\* values or with very high levels of iron overload (46).

The second oral chelator to achieve approval, Deferasirox, is a member of a new class of tridentate iron chelators, the bis-hydroxyphenyl-triazoles. Deferasirox (ICL670, Exjade), is a once-daily administered oral iron chelator, which has shown to be effective in both adults and children in extensive clinical trials. Studies have shown it is as effective as desferrioxamine but without the adverse effects of deferiprone (47). Common adverse events were generally mild, including transient gastrointestinal events and skin rashes (48). The drug is now licensed for use in most countries for use in children aged 2 years and older with transfusional iron overload. However, the cost of therapy using deferasirox is very high, with the cost per patient per year calculated to be as high as \$80,000, which poses problems for the developing world where the majority of patients live (49).

Deferiprone is much less expensive than deferasirox, but must be taken several times a day and requires more safety monitoring (50).

Other side effects of transfusions include hepatitis and cytomegalovirus infections. Isoimmunization to minor blood groups may occur, but careful selection of donors may decrease this risk. Sensitization to white cell or plasma antigens may be decreased by using blood with the white cells removed. Urticaria may be treated with antihistamines, as well as epinephrine, prior to and during transfusion. Febrile reactions may require antipyretics and occasionally, if severe, steroids. Recombinant  $\alpha$ -interferon is the only effective therapy for hepatitis C infection, being effective only in about 25% of infected patients. However, when combined with ribavirin, a guanosine analog, it produces sustained viral clearance in up to 45% of younger thalassemia major patients. Finally, the increased rate of erythropoiesis can lead to increased folic acid requirements. If folate deficiency occurs, it may cause increased anemia; however, deficiency is easily avoided by daily oral administration of folic acid.

**71.9.10.3 Infection.** Splenectomy may be avoided by hypertransfusion therapy; many patients reaching adolescence who received early hypertransfusion therapy do not require it. However, splenectomy may be necessary to alleviate hypersplenism with worsening of the anemia or pain due to progressive splenomegaly or infarction of the spleen. Splenectomy should be delayed until the age of 5 years because, as discussed previously, splenectomized children, especially those under 6 years of age, are at risk for life-threatening infections. Pneumococcal vaccine, as well as prophylactic penicillin, should be used in such children, and suspected infections should be treated aggressively.

**71.9.10.4 Bone Marrow Transplantation.** Bone marrow transplantation offers the only cure for  $\beta$ -thalassemia major. Allogeneic bone marrow transplantation using related donors has been used in a large number of patients, predominantly in Europe, with studies showing approximately 80% of patients surviving long term and of these, nearly 90% being cured (3). Better outcomes are associated with adequate iron chelation and the absence of significant hepatic disease, although survival and disease-free survival rates still vary considerably between different centers. The post-transplant complications involve acute and chronic graft-versus-host disease and the persistence of host hematopoietic cells (mixed chimerism). The major limitation of bone marrow transplantation is the lack of an identical HLA-identical sibling donor for most affected patients. Future and experimental approaches to marrow transplantation in patients with thalassemia include transplantation from matched unrelated donors, cord blood transplantation, and in utero transplantation. Good success rates have been reported for a limited number of transplantations from carefully matched unrelated donors (51) and umbilical cord blood

transplantation from a related donor offers a good possibility of success with a lowered risk of graft-versus-host disease (52).

In theory, gene therapy using autologous bone marrow has the potential to cure thalassemia major permanently without the limitations of finding a matched donor or the risk of graft-versus-host disease. In practice, progress on gene therapy for  $\beta$ -thalassemia has been slow as globin gene vectors with the required regulatory elements have proved challenging to design and produce (53). However, a major advance was achieved when a lentiviral vector was used to correct mouse  $\beta$ -thalassemia (54) and current research is focussed on enhancing the safety and efficiency of lentivirus vectors for correcting of the molecular defect in hematopoietic stem cells or the use of homologous recombination instead of gene transfer. A clinical trial using a lentiviral vector is in progress in France while other trials are in development (55).

**71.9.10.5 Augmentation of Fetal Hemoglobin.** As in sickle-cell syndromes, a number of pharmacological agents are being used to elevate hemoglobin F in patients with homozygous  $\beta$ -thalassemia with the aim of increasing Hb F to levels high enough to prevent all complications of the disease. These agents, including 5-azacytidine, hydroxyurea and butyrate compounds, induce Hb F synthesis by different mechanisms (56). Although a significant amelioration of the anemia has been achieved in some thalassemia patients, the effects of treatment have been more modest compared to the treatment of sickle-cell disease, and better agents that can induce higher levels of Hb F are still needed.

The first trials with both hydroxyurea and butyrate derivatives showed only modest increases in hemoglobin without any apparent beneficial effects, apart from the case of one patient with Hb Lepore/ $\beta$ -thalassemia. Further studies with hydroxyurea treatment of patients with thalassemia intermedia and Hb E/ $\beta^0$ -thalassemia showed a small but significant increase of both Hb F and hemoglobin concentration (57), which could be increased further with a combination therapy of hydroxyurea and sodium phenylbutyrate. However, the treatment of patients with thalassemia major appears to be less effective (58). Although it has been reported that some patients have responded with a sufficient rise in Hb level to shift the patient into stable transfusion-free condition, the majority do not (59). A study of the treatment with hydroxyurea of Iranian thalassemia major patients has revealed that the responsive patients were those with mutations linked to specific  $\beta$ -gene haplotypes, in particular the ones linked to the -158  $G\gamma$  C→T nondeletion HPFH allele (the XmnI polymorphism) (60). More long-term in vivo trials on Hb F inducers are required to investigate dosing regimens and combinations of drugs, together with the identification of specific  $\beta$ -thalassemia mutations that may be particularly responsive to therapy.

### Biography

**Dr John Old** is a consultant clinical scientist in the Molecular Haematology department of the John Radcliffe Hospital in Oxford, UK, and holds the honorary post of Reader in Haematology at Oxford University. He is the Director of the National Hemoglobinopathy Reference Service, established in 1982 by the Department of Health to carry out first trimester prenatal diagnosis for the hemoglobinopathies, and diagnose difficult diagnostic cases by DNA analysis. He is registered as a clinical scientist with the Health Professions Council and is a Fellow of the Royal College of Pathologists.

After completing a PhD in biochemistry at Liverpool University in 1974, he worked as a research scientist in Professor Sir David Weatherall's laboratory at the University of Oxford for 8 years, investigating the molecular basis of the thalassemias and the diagnosis of globin gene mutations, before changing direction to set up a molecular diagnostic laboratory for hemoglobinopathies and develop new diagnostic techniques for carrier detection and prenatal diagnosis. He has collaborated with many international laboratories on thalassemia research and diagnostic techniques, including assisting centers in India and Cyprus to set up national screening and prevention programmes for  $\beta$ -thalassemia, and has published 165 papers and articles on the subject of the hemoglobinopathies. He has also held many professional appointments, including Vice-President of the Royal College of Pathologists, a Director of the Board of Clinical Pathology Accreditation (UK) Ltd and a Council Member of the Health Professions Council.

## Other Hereditary Red Blood Cell Disorders

*Bertil Glader*

Department of Pediatrics and Pathology, Stanford University School of Medicine,  
Stanford, CA, USA

### 72.1 HEMOLYSIS DUE TO HEREDITARY RED BLOOD CELL ENZYME DISORDERS

The majority of erythrocyte enzyme abnormalities associated with hemolysis is due to gene mutations that cause deficiency of an enzyme critical for red blood cell (RBC) function. The enzyme deficiency in these cases may be due to decreased enzyme synthesis, the presence of an enzyme with abnormal kinetics, or the presence of a physically unstable enzyme whose function changes as cells age (which is important since mature, anucleate erythrocytes are incapable of new protein synthesis). In rare cases hemolysis is not due to an enzyme deficiency but rather a consequence of increased enzyme activity that secondarily has deleterious effects on cell metabolism (e.g. adenosine deaminase (ADA) excess). In addition to enzymopathies that cause hemolysis, some enzyme deficiencies have no adverse effects on RBC function (e.g. enolase, lactic dehydrogenase, and 6-phosphogluconate dehydrogenase deficiency), or if they occur in patients with hemolytic anemia, it is not clear that the enzyme deficiency and hemolysis are causally related (e.g. glutathione peroxidase and glutathione reductase deficiency). The major causes of hemolysis due to hereditary RBC enzyme defects are abnormalities in the hexosemonophosphate (HMP) shunt and glutathione metabolism, glycolytic enzyme deficiencies, and abnormalities in purine and pyrimidine metabolic enzymes (Figure 72-1).

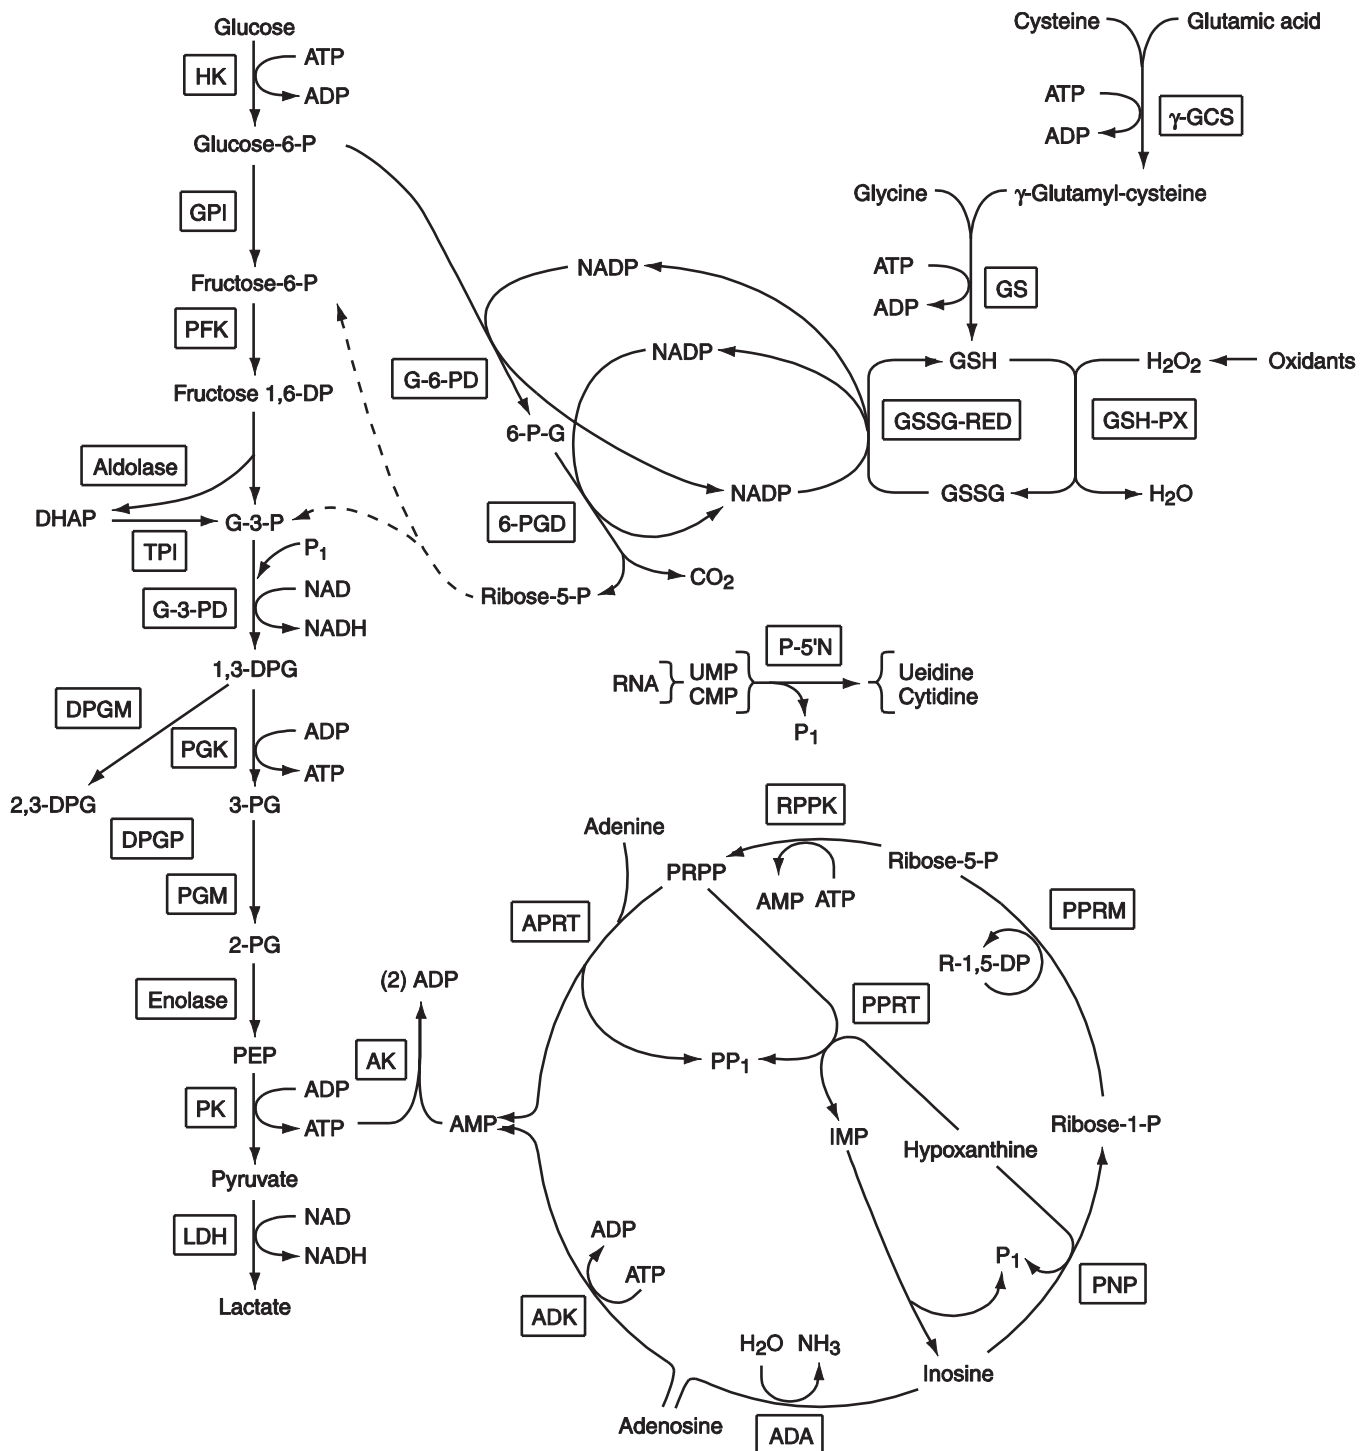

#### 72.1.1 Hemolysis due to Disorders of the Hexosemonophosphate Shunt and Glutathione Metabolism Pathway

The HMP shunt pathway metabolizes 5–10% of the glucose utilized by RBCs and this is critical for protecting RBCs against oxidant injury. The HMP pathway is the only source of reduced nicotinamide adenine dinucleotide phosphate (NADPH), a cofactor important in

glutathione metabolism. RBCs contain relatively high concentrations of reduced glutathione (GSH), a sulfhydryl containing tripeptide ( $\gamma$ -glutamylcysteinylglycine) that functions as an intracellular reducing agent, protecting cells against oxidant injury. Oxidants, such as superoxide anion ( $O_2^-$ ) and hydrogen peroxide ( $H_2O_2$ ), are produced by exogenous factors (i.e. drugs, infection) and also are formed within red cells as a consequence of reactions of hemoglobin with oxygen. Under conditions where these oxidants accumulate within the RBC, cellular proteins are altered thereby leading to lethal cell injury. Under normal circumstances this does not occur since GSH, in conjunction with the enzyme glutathione peroxidase (GSH-Px), rapidly inactivates these oxidants. During the detoxification process, however, GSH itself is converted to oxidized glutathione (GSSG), and GSH levels fall. To sustain protection against persistent oxidant injury, GSH levels must be maintained, and this is accomplished by glutathione reductase (GSSG-Rx), which catalyzes the reduction of GSSG to GSH. This reaction requires the NADPH generated by glucose-6-phosphate dehydrogenase (G6PD), the first enzymatic reaction of the HMP shunt. Thus, it is the tight coupling of the HMP shunt and glutathione metabolism that is responsible for protecting intracellular proteins from oxidative assault. Almost all hemolytic episodes related to altered HMP shunt and glutathione metabolism are due to G6PD deficiency. Rare cases of hemolysis associated with decreased GSSG-Rx activity, GSH-Px deficiency, and deficiencies of GSH synthetic enzymes have been described.

##### 72.1.1.1 Glucose-6-Phosphate Dehydrogenase Deficiency.

**72.1.1.1.1 Prevalence and Geographic Distribution.** This is the most common RBC enzyme abnormality associated with hemolysis (1–4). This RBC enzyme disorder affects millions of people throughout the world,

**FIGURE 72-1** Glycolysis. Enzymes: HK, hexokinase; GPI, glucosephosphate isomerase; PFK, phosphofructokinase; TPI, triosephosphate isomerase; G3PD, glyceraldehyde-3-phosphate dehydrogenase; PGK, phosphoglycerate kinase; DPGM, 2,3-diphosphoglycerate mutase; DPGP, 2,3-diphosphoglycerate phosphatase; PGM, phosphoglycerate mutase; PK, pyruvate kinase; LDH, lactate dehydrogenase. Substrates: 1,3-DPG, 1,3-diphosphoglycerate; G-3-P, glyceraldehyde-3-phosphate; DHAP, dihydroxyacetone phosphate; 3-PG, 3-phosphoglycerate; 2-PG, 2-phosphoglycerate; PEP, phosphoenolpyruvate; HMP shunt and glutathione metabolism. Enzymes: G-6-PD, glucose-6-phosphate dehydrogenase; 6-PGD, 6-phosphogluconate dehydrogenase; GSSG-Red, glutathione reductase; GSH-Px, glutathione peroxidase; GS, glutathione synthetase; γGCS, gamma-glutamyl-cysteine synthetase. Substrates: G-3-P, glyceraldehyde-3-phosphate; DHAP, dihydroxyacetone phosphate; R-5-P, ribose-5-phosphate; 6-PG, 6-phosphogluconate; GSH, reduced glutathione; GSSG, oxidized glutathione. Purine and pyrimidine metabolism. Enzymes: ADA, adenosine deaminase; ADK, adenosine kinase; AK, adenylylate kinase; APRT, adenine phosphoribosyl transferase; RPPK, ribopyrophosphoryl kinase; PPRM, pyrophosphoribosyl mutase; PPRT, pyrophosphoribosyl transferase; PNP, purine nucleoside phosphorylase; P-5'N, pyrimidine 5' nucleotidase. Substrates: AMP, adenosine monophosphate; IMP, inosine monophosphate.

the highest frequency occurring in Mediterranean countries, Africa, and Asia. Approximately 10–15% of African-Americans are deficient in erythrocyte G6PD activity, and this is similar to the 20% incidence reported in Nigeria. In contrast, the incidence of G6PD deficiency in Mediterranean individuals is much more variable, ranging from approximately 2% in Sicily to over 20% in the Greek Island of Rhodes. As many as 60–70% of Kurdish Jews may be affected and in the Asian male population, the incidence of G6PD deficiency is estimated to be 14% in Cambodia, 6% in South China, 3% in India, and less than 0.1% in Japan.

It is intriguing that the worldwide distribution of G6PD deficiency is similar to that for malaria, and it has long been considered that the gene for G6PD deficiency may be protective against malaria (5). Partial indirect support for this is that G6PD deficiency in Sardinia is more common at sea level compared to higher elevations, and this also parallels the endemicity of malaria. In addition, it has been observed that female heterozygotes for G6PD deficiency (who therefore have normal and G6PD-deficient RBC) have more malaria parasites in normal erythrocytes compared to their own G6PD-deficient cells. The reason for this balanced polymorphism is unknown and remains a subject for interesting speculation.

**72.1.1.1.2 Biochemistry.** Several hundred different variants of G6PD have been described, each of which is thought to differ in their biochemical properties (e.g. kinetic activity, electrophoretic mobility, pH optima, and/or affinity for substrate and/or cofactor). The World Health Organization (WHO) has classified the different G6PD variants on the basis of enzyme deficiency and severity of hemolysis (6):

Class I: severe deficiency with chronic hemolytic anemia;

Class II: severe deficiency with intermittent hemolysis;

Class III: moderate deficiency with intermittent hemolysis;

Class IV: no deficiency or hemolysis.

The normal wild-type enzyme is designated G6PD<sup>B</sup> and is found in almost all Caucasians and a majority of black people. It has normal catalytic activity and is not associated with hemolysis (class IV). In addition, there are over 400 different biochemical variants that are designated by geographic or trivial names. Commonly encountered variants include the following:

- (1) G6PD<sup>A+</sup> is found in 20% of African-Americans. It has normal catalytic properties and does not cause hemolysis (class IV). It differs from G6PD<sup>B</sup> in that it has a much faster electrophoretic mobility. The structure of G6PD<sup>A+</sup> differs from that of G6PD<sup>B</sup> by the substitution of one amino acid, an asparagine for aspartate.
- (2) G6PD<sup>A-</sup> is the most common variant associated with mild to moderate hemolysis (class III), and is found in 10–15% of African-Americans. Its electrophoretic

mobility is identical to that of G6PD<sup>A-</sup>. This is an unstable enzyme and its catalytic activity is decreased in older RBCs. Hence, this variant is designated G6PD<sup>A-</sup> compared with G6PD<sup>A+</sup>.

- (3) G6PD<sup>Mediterranean</sup> is the most common abnormal variant found in Caucasians, particularly those whose origins are in the Mediterranean area and the Middle East. The electrophoretic mobility of G6PD<sup>Mediterranean</sup> is identical to that of G6PD<sup>B</sup>, but its catalytic activity is markedly reduced and hemolysis can be severe (class II).

- (4) G6PD<sup>Canton</sup> is a variant seen in Asians. Its biochemical properties are very similar to those of G6PD<sup>Mediterranean</sup>.

Advances in molecular biology have enhanced our understanding of the abnormalities of G6PD deficiency (4,6). In view of the numerous biochemical variants that have been described, it is no surprise that over 100 different point mutations and deletions in the G6PD gene have been identified (7,8). However, large deletions or frameshift mutations have not been identified, suggesting that complete absence of G6PD might be lethal. The mutations on the gene do not appear to be random and most of the variants associated with chronic hemolysis (class I) have abnormalities in the NADP or glucose-6-phosphate binding site of the gene.

An interesting example of how molecular biology has enhanced our understanding relates to G6PD<sup>A-</sup>. This once was thought to represent a single unstable variant found in black people throughout the world. However, molecular analysis now has demonstrated that G6PD<sup>A-</sup> may have more than one genotype. In all cases there is a mutation at nucleotide 376 (A→G), which also is the nucleotide substitution characteristic of G6PD<sup>A+</sup>. In addition, however, the G6PD<sup>A-</sup> variants have a second mutation, and in the majority of cases it is at nucleotide 202 (G→A), while in some the second substitution is at nucleotide 680 (G→T) or at nucleotide 968 (T→C). Thus, the G6PD<sup>A-</sup> variant, once thought to be a single homogeneous mutation in Africans, now turns out to represent at least three different genotypes (6). Moreover, a number of G6PD variants originally described in non-Africans are now found to have one of the known G6PD<sup>A-</sup> mutations (Table 72-1). For example, G6PD<sup>Betica</sup>, a Spanish variant, and G6PD<sup>Matera</sup>, an Italian variant, have demonstrated base substitutions at nucleotides 202 and 376, identical to the more common G6PD<sup>A-</sup> variant. They are examples, therefore, of G6PD<sup>A-</sup>. There are several other variants that appear clinically heterogeneous but have been found to be genetically more uniform. For example, G6PD<sup>Mediterranean</sup> involves many different ethnic groups, although most subjects have the same genetic defect, a single base substitution (C→T) at nucleotide 563. Moreover, just as in the case of G6PD<sup>A-</sup>, many of the known biochemical variants turned out to have the same molecular defect as G6PD<sup>Mediterranean</sup> (Table 72-1).

**TABLE 72-1 Biochemical, Epidemiological, and Clinical Features of Select G6PD Variants**

**72.1.1.1.3 Pathophysiology.** As normal RBCs age, the intracellular activity of G6PD<sup>B</sup> decreases. Despite this loss of enzyme activity, normal old RBCs contain sufficient G6PD activity to generate NADPH and thereby maintain GSH levels in the face of oxidant stress. The defect in Africans with G6PD deficiency is due to increased enzyme instability of G6PD<sup>A-</sup> such that young RBCs have relatively normal enzyme activity, whereas older red cells are severely G6PD deficient. The clinical correlate of this is that hemolysis in patients with G6PD<sup>A-</sup> generally is mild and is limited to the older deficient erythrocytes. In contrast, the enzymatic defect in G6PD<sup>Mediterranean</sup> is due to a much greater enzyme instability, and RBCs of all ages are grossly deficient. Consequently, the entire RBC population of individuals with G6PD<sup>Mediterranean</sup> is susceptible to oxidant-induced injury, and this can lead to severe hemolysis.

The clinical observation that the severity of hemolysis due to G6PD deficiency is worse in males compared to females is consistent with the fact that the gene for G6PD is located on the X chromosome. Males have only one type of G6PD, whereas females may have two different biochemical types of enzyme. According to the Lyon hypothesis, however, only one X chromosome is active in any given somatic cell (9). Thus, although females may have two different G6PD variants, any given RBC contains only one type of G6PD. Depending on the degree of lyonization, the mean RBC enzyme activity in females who carry a gene for G6PD deficiency may be normal, moderately reduced, or grossly deficient. The G6PD-deficient cells in females, however, are as vulnerable to hemolysis as are the enzyme-deficient RBCs in males.

**72.1.1.1.4 Clinical Features.** With the most prevalent G6PD variants (G6PD<sup>A-</sup> and G6PD<sup>Mediterranean</sup>),

severe hemolysis occurs only after exposure to certain offending agents. The steady state is not associated with anemia or any alteration in blood morphology. Sudden destruction of the older, more deficient erythrocytes is triggered by drugs having a high redox potential and by selected infectious or metabolic perturbations. The characteristics of an acute hemolytic episode are sudden pallor, jaundice, dark urine with or without abdominal and back pain, and an abrupt decrement of 3–4 g/dl in hemoglobin concentration. In response to anemia, RBC production increases and an increase in reticulocytes is apparent within 5 days after the onset of hemolysis. In cases of G6PD<sup>A-</sup> the anemia is self-limited because the older, vulnerable population of erythrocytes is replaced by younger RBC with sufficient G6PD activity to withstand an oxidative assault. In contrast, the hemolysis occurring with G6PD<sup>Mediterranean</sup> is more severe because this variant enzyme has a very short intraerythrocytic half-life, and thus a larger population of circulating erythrocytes is vulnerable to injury. For practical purposes, the most important consequences of G6PD deficiency are limited to the RBCs. In rare cases of G6PD deficiency in Caucasians, there is a concurrent decrease in the enzyme activity of leukocytes, but this usually is of little clinical significance.

**72.1.1.1.5 Drugs.** The discovery of G6PD deficiency as a cause of hemolysis originally followed the observation that some African-American soldiers developed hemolysis after receiving primaquine phosphate for malaria prophylaxis (10). Subsequently, numerous other drugs have been implicated as causative agents and the common denominator of these drugs is that they interact with hemoglobin and oxygen, thus accelerating the intracellular formation of H<sub>2</sub>O<sub>2</sub> and other oxidizing radicals.

**72.1.1.1.6 Infections.** Hepatitis, salmonellosis, and pneumonia are established inciting causes of hemolysis in G6PD deficiency, but virtually any type of infection can lead to accelerated destruction of G6PD-deficient red cells. A reasonable explanation for this relationship between infection and hemolysis is that oxidants generated by phagocytosing macrophages diffuse into the extracellular medium and pose an oxidative threat to G6PD-deficient erythrocytes.

**72.1.1.1.7 Favism.** The fact that exposure to the fava bean (*Vicia fava*, broad bean) is toxic and potentially fatal for some individuals allegedly has been known since the time of Pythagoras. Hemolysis following exposure to fava beans occurs in G6PD-deficient Caucasians and Asians, but rarely ever is seen in African individuals. It occurs primarily in children. Hemolytic episodes can occur after exposure to fava bean pollen, after ingesting fresh fava beans, and following consumption of dried beans. It also can occur in babies who nurse following maternal exposure (11). It is thought that unstable pyrimidine glycosides (isouramil and divicine) in fava beans are the active oxidants responsible for hemolysis (12). Favism does not occur in all susceptible G6PD individuals, and it is thought that an additional genetic factor is involved, presumably related to how fava bean oxidants are metabolized.

**72.1.1.1.8 Neonatal Jaundice.** Hyperbilirubinemia is a well-documented consequence of G6PD deficiency (class II) in Caucasian and Asian neonates. This hyperbilirubinemia often occurs in the absence of any obvious exogenous oxidant stress, and there often is no evidence of hemolysis. It is now recognized that very severe hyperbilirubinemia in neonates with G6PD deficiency often occurs in those who also carry the gene for Gilbert syndrome (13,14). African-American infants with G6PD<sup>A-</sup> appear to have a much reduced incidence and severity of hyperbilirubinemia, although significant hemolysis and severe hyperbilirubinemia can occur (15). Of interest, black infants in Africa have an increased incidence of neonatal hyperbilirubinemia, also associated with kernicterus and severe neurologic injury or death. Since black Africans and African-Americans have the same G6PD<sup>A-</sup> genotypes, the adverse outcomes in Africa are thought to relate to local customs and differences in oxidant exposure. This is also seen with other ethnic groups. The incidence of hyperbilirubinemia in G6PD-deficient infants born in Australia to Greek immigrants is lower than that noted in deficient infants in Greece (16). Herbs used in traditional Chinese medicine, clothing impregnated with naphthalene, and chemicals taken by the mother in late gestation all have been implicated as the inciting oxidant in selected cases of G6PD deficiency.

**72.1.1.1.9 Diagnosis.** The diagnosis of G6PD deficiency is made by a spectrophotometric assay or screening test that utilizes hemolysate as a source of enzyme. Regardless of the specific test used, however, false-negative reactions may occur if the most enzymatically

deficient RBCs have been removed by hemolysis. This generally is not critical in testing male Caucasians and Asians, but can be a problem in diagnosing people of African heritage, especially during the reticulocytosis following acute hemolysis. In these cases it sometimes is necessary to wait until the hemolytic crisis is over and reevaluate for G6PD deficiency in 2–3 months when the RBC mass has been repopulated with cells of all ages.

**72.1.1.1.10 Treatment.** RBC transfusions are appropriate in those rare circumstances in which signs and symptoms of anemia indicate severe cardiovascular compromise. In the usual case, however, therapeutic endeavors are directed toward minimizing potential sources of oxidant stress. The most common drugs implicated are seen in Table 72-2. Most individuals with G6PD deficiency have an almost normal RBC survival and hemolytic anemia occurs only with oxidant stress, whereas there are rare individuals with G6PD variants who manifest chronic hemolysis. Common clinical characteristics of these patients with class I type of G6PD deficiency include mild anemia, neonatal jaundice, gallstones, and splenomegaly. These individuals always have evidence of hemolysis (reticulocytosis, hyperbilirubinemia).

**72.1.1.1.11 Screening.** Generalized screening for G6PD deficiency does not exist because the most common variants responsible for acquired hemolytic anemia pose little health hazard. However, recent data from the USA Kernicterus Registry indicate that over 30% of kernicterus cases are associated with G6PD deficiency (17). These observations thus have raised the question of whether G6PD testing should be part of newborn screening programs (18). In the United States, the only required newborn screening for G6PD deficiency occurs in the District of Columbia. It could be argued that certain Mediterranean and Middle East populations might benefit from knowing their G6PD status, and could thereby avoid obvious oxidant exposures. Routine blood bank screening appears to be unwarranted and G6PD deficiency is not considered a major problem in transfusion medicine. However, in premature infants, simple transfusions with G6PD-deficient red cells have been associated with hemolysis and severe hyperbilirubinemia requiring exchange transfusion. Moreover, massive intravascular hemolysis has occurred in an Indian neonate following an exchange transfusion with G6PD-deficient blood (19). In view of these occurrences, it has been recommended that in areas where G6PD deficiency (presumably class II variants) is common, donor blood should be screened for the enzyme before transfusing premature infants or using the blood for a neonatal exchange transfusion. Of interest, hemolysis has occurred in bone marrow transplant recipients who have received their stem cells from a G6PD-deficient donor (20).

**72.1.1.2 GSSG-Rx Deficiency.** Partial deficiency of erythrocyte GSSG-Rx activity, although not associated with hemolysis, has been described in a variety of hematologic disorders, malignancies, liver disease, and

malnutrition. However, it now appears that most GSSG-Rx deficiencies reported to date are a reflection of riboflavin deficiency since flavin adenine dinucleotide (FAD) is an essential cofactor for maximal GSSG activity. Only one clear case of hemolysis associated with GSSG-Rx deficiency has been described (21).

**72.1.1.3 GSH-Px Deficiency.** Rare cases of hemolysis in association with moderate deficiency of erythrocyte GSH-Px activity have been described in adults, children, and newborn infants. However, the general consensus now is that GSH-Px deficiency may not be a cause of hemolysis or other hematologic problems. Many healthy normal individuals, particularly those of Jewish or Mediterranean ancestry, have reduced GSH-Px activity without evidence of hemolysis (22). Moreover, low GSH-Px activity, in the absence of hemolysis, also has been observed in normal people from New Zealand with selenium (Se) deficiency. (Se is an integral part of GSH-Px.) In view of these observations, it is unlikely that GSH-Px deficiency is a cause of significant hemolysis.

## 72.1.2 Deficiencies of Glutathione Synthetic Enzymes

Glutathione is actively synthesized in RBCs and has an intracellular half-life of only 4 days, in part due to cellular efflux of GSSG. RBCs are capable of de novo GSH synthesis and this is accomplished by two critical enzymes (Figure 72-1). Gamma-glutamyl-cysteine synthetase ( $\gamma$ GCS) catalyzes the first step in GSH synthesis, the formation of gamma-glutamyl-cysteine from glutamic acid

and cysteine. Glutathione synthetase (GS) catalyzes the formation of GSH from glutamyl-cysteine and glycine. In many tissues, but not RBC, these two enzymes are part of the gamma-glutamyl cycle, which is involved with the synthesis and degradation of GSH and also thought to have a role in amino acid transport across cell membranes. Hereditary hemolytic anemia, characterized by reduced GSH content, has been reported in patients with deficiencies of both gamma  $\gamma$ GCS and GS activity.

**72.1.2.1 Gamma-Glutamyl-Cysteine Synthetase Deficiency.** This rare hemolytic anemia was first described in two adults who were brother and sister (23). Both these patients had a lifelong history of anemia, intermittent jaundice, cholelithiasis, and splenomegaly. They also manifested severe neurologic dysfunction, and a generalized aminoaciduria (24). This disorder appeared to be an autosomal recessive condition and, in the family studied, presumed carriers had reduced gamma  $\gamma$ GCS activity, although erythrocyte GSH levels were normal. Hemolytic anemia was seen only in the homozygous state where erythrocyte GSH levels are approximately 5% of normal, and there was markedly reduced  $\gamma$ GCS activity. Subsequent to the initial case report, an additional six patients have been identified (13,25–27). In all these cases hemolysis was the only clinical manifestation and no neurologic abnormalities have been noted since the original case report over 30 years ago (28,29).

**72.1.2.2 GS Deficiency.** This disorder has been described in association with hemolysis in over 70 patients (27,29,30). There are three types of GS deficiencies with different clinical manifestations. In the mild

**TABLE 72-3 Features of Glycolytic and Nucleotide Enzymopathies**

Enzymopathy	Approximate Fraction of Enzymopathies (a)	Mode of Inheritance (b)	Effects of (c)
HK	<1%	AR	Mild/severe CNSHA
GPI	3–5%	AR	Moderate/severe CNSHA
PFK	<1%	AR	Mild CNSHA +/-myopathy
Aldolase	<1%	AR	Mild/moderate CNSHA, psychomotor retardation
TPI	<1%	AR	Moderate/severe CNSHA, severe neurologic deficits
PGK	<1%	X-linked	Mild/severe CNSHA, psychomotor retardation, seizures, extra pyramidal disease
PK (48)	80–90%	AR	Moderate/severe CNSHA
P5'N	2–3%	AR	Moderate CNSHA
ADA excess	<1%	AD	Mild CNSHA
AK	<1%	AR	CNSHA

AR, autosomal recessive; AD, autosomal dominant; CNSHA, chronic nonspherocytic hemolytic anemia.

Data from Glader (2004). Approximate estimates derived from several sources (Beutler 1979; Tanaka and Zerez 1990; Mentzer 2003).

type, significant enzyme deficiency is limited to erythrocytes. The defect is due to mutations that affect the stability of the enzyme. Other nucleated cells that also have this defect can compensate for this instability because they are capable of new protein synthesis. In contrast, anucleate red cells are unable to synthesize more enzyme and GSH levels are depleted. The major manifestations of this deficiency are splenomegaly, intermittent jaundice, and compensated hemolytic anemia. In moderate cases, GS deficiency is generalized to other tissues in addition to red cells. Clinical problems include hemolytic anemia, persistent metabolic acidosis presenting in the newborn period, and overproduction of 5-oxoproline with oxoproluria. In the most severe cases there also are organic neurologic defects and mental retardation (29,31,32). Deficiency of GS appears to be an autosomal recessive disorder. Relatives of affected patients have reduced enzyme activity, but erythrocyte GSH content is normal and there are no hematologic problems. The possibility of this disorder is suspected in patients with hemolytic anemia and markedly reduced RBC GSH content. A case of a newborn with GSS deficiency was recognized when tandem mass spectrometry-based newborn screening revealed greater than a 10-fold elevation of 5-oxoproline in dried blood (33). Virtually no GS activity is detected in homozygous or compound heterozygous deficient individuals. In those GS-deficient individuals with oxoprolinemia, oral bicarbonate administration is necessary to control the acidosis. The gene for GS is located on chromosome 20q11. In one study of 41 patients, 27 different GS mutations were identified and almost all were missense or splice mutations (29).

### 72.1.3 Hemolysis Associated with Glycolytic Enzyme Abnormalities

Since mature RBCs lack mitochondria, glycolysis is the only metabolic pathway capable of adenosine triphosphate (ATP) synthesis (Figure 72-1). The cause of

hemolysis in RBC glycolytic defects is not known, but is thought to be due to decreased function of some vital ATP-dependent process. Hemolytic anemias due to glycolytic enzymopathies are relatively rare, affecting only a few thousand individuals in the world (1,34,35). Abnormalities in virtually every glycolytic enzyme have been described, although 80–90% of all cases associated with hemolysis are due to pyruvate kinase deficiency (Table 72-3). In some of these disorders, the enzyme deficiency is not limited to RBCs but also includes leukocytes, platelets, muscle, and/or neural tissue. Most glycolytic enzymopathies manifest an autosomal recessive pattern of inheritance. Heterozygotes almost always are hematologically normal, although their RBCs contain less than normal levels of enzyme activity. It once was thought that hemolysis occurred only in those individuals who were homozygous for the enzyme deficiency. However, true homozygotes for a given mutant enzyme now are known to be less common, and usually restricted to consanguineous kindred. The vast majority of cases of hemolytic anemia due to glycolytic enzyme deficiencies are a consequence of double heterozygosity for two different enzyme variants, and this accounts for the diverse biochemical and clinical heterogeneity of the red cell glycolytic enzymopathies. The one exception to this autosomal inheritance is phosphoglycerate kinase (PGK) deficiency, which is an X-linked disorder. Clinical manifestations of hemolysis include chronic anemia, reticulocytosis, and some degree of hyperbilirubinemia. The magnitude of anemia frequently is increased during viral infections and this can be due to increased hemolysis, or transient aplastic crises associated with viral infections. Most children with RBC glycolytic defects have a history of neonatal jaundice, many may require an exchange transfusion, and rarely kernicterus has been reported. Unlike hemolysis associated with G6PD deficiency, the jaundice noted in pyruvate kinase (PK)-deficient infants invariably is associated with anemia and often

with splenomegaly. There are no specific morphologic abnormalities to suggest an RBC glycolytic enzymopathy. The possibility of a glycolytic enzymopathy exists when chronic hemolytic anemia cannot be explained by the more common causes of hemolysis (i.e. hereditary spherocytosis (HS) or hemoglobinopathies). Screening tests are readily available, but are of limited value, frequently yielding false-negative results. An inherent problem in the diagnosis of glycolytic enzymopathies is that the most severely affected cells usually are removed *in vivo* (i.e. hemolyzed). For this reason, it sometimes is helpful to study parents and other family members for the presumed heterozygous state of the enzyme deficiency. In some cases DNA-based molecular diagnostic tests may be available.

Therapy for RBC glycolytic defects is similar to that of other chronic hemolytic anemias. Severely anemic patients often benefit from splenectomy. However, the response to splenectomy is only partial and, in most cases, hemolysis usually continues, although RBC transfusion requirements decrease. Cholelithiasis is a constant problem and all patients with glycolytic enzymopathies should have periodic gallbladder ultrasound examinations, even after the spleen is removed. The most common of these rare disorders are summarized in the following paragraphs and in Table 72-3.

**72.1.3.1 PK Deficiency.** PK catalyzes one of the two glycolytic reactions responsible for ATP production. There are two different PK-encoding genes in humans. One of these is PKLR (which is expressed in the liver and RBCs) and this resides on chromosome 1. The second is PKM2 (which is expressed in leukocytes and muscle) and this resides on chromosome 15. PKLR has been cloned and sequenced (36). The hemolytic anemia associated with PK deficiency is due to mutations of the PKLR gene and over 100 different mutations have been identified (37,38). Most of these are due to point mutations, the large majority occurring at nucleotide 1529 (39). A significant fraction of affected Caucasians (30–40%) have at least one mutation at nucleotide 1529 (G→A) resulting in an amino acid change at the 510 position (Arg→Gln). The variable phenotypic expression of PK deficiency undoubtedly reflects the heterogeneity of these different PK mutants. Hemolysis is seen in the homozygous state, but more commonly, it occurs in the presence of double heterozygosity for two different abnormal variants. Simple heterozygotes for abnormal PK variants are hematologically normal.

Most cases of PK deficiency have been reported from Northern Europe, the United States, and Japan; however, the disorder occurs worldwide (35,38,40). Using molecular biology techniques with four common PK mutations, it has been estimated that the prevalence of PK deficiency is 51 cases per million (0.01%) white population (41). A particularly high frequency exists among the Pennsylvania Amish, in whom the disorder can be traced to a single immigrant couple (42).

The degree of hemolysis in PK deficiency varies greatly and often is severe enough to require frequent or regular RBC transfusions. Almost all affected patients demonstrate a beneficial response to splenectomy. The anemia that persists following splenectomy generally is well tolerated and the need for transfusions is markedly reduced. In rare patients with severe hemolysis stem cell transplantation (BMT) has been successfully employed (43).

In families with a child with PK deficiency, the issue of prenatal diagnosis in subsequent pregnancies is a matter of concern. Biochemical techniques have been used successfully to assay for red cell PK deficiency at 30 weeks gestation (44). However, biochemical enzyme assays have limited utility in the prenatal diagnosis of PK deficiency, and direct DNA analysis is preferred whenever possible (39). In particular this should be helpful in diagnosing those fetuses with the 1529A mutation, thought to account for 45% of cases of PK deficiency in non-Gypsy Caucasians. The large number of cases of PK deficiency in Gypsies is associated with a unique deletional mutation that also could be used for molecular diagnosis.

**72.1.3.2 Glucose Phosphate Isomerase Deficiency.** This enzyme deficiency, first reported by Baughan et al. in 1968, is now recognized as the second most common glycolytic enzymopathy associated with hemolysis. Since the first description of the disorder more than 50 cases have been reported (1,35,45). Just as for PK deficiency, many more cases probably exist but are not published or listed in any rare disease registry. It is estimated that 0.2% of North Americans are heterozygous for a glucose phosphate isomerase (GPI) mutant. The gene for GPI is located on chromosome 19; it has been isolated and sequenced. Several different gene mutations of GPI deficiency associated with hemolysis have been identified (45,46). In most cases associated with hemolysis, the defect is due to an unstable enzyme. The clinical manifestations of this disorder are mostly limited to the RBCs, although neurologic impairment has been described in some cases (45). Just as is the case for PK deficiency, hemolysis occurs in GPI homozygotes or compound heterozygotes. Hemolytic anemia due to GPI deficiency has been reported as a cause of neonatal hydrops fetalis (47). Usually there is a partial response to splenectomy. Prenatal diagnosis of GPI by enzymatic assay previously has been demonstrated (48,49); however, in a family with a known mutation direct molecular analysis is preferable.

**72.1.3.3 Hexokinase Deficiency.** Deficiency of red cell hexokinase activity is a rare cause of hemolysis that now has been identified in over 20 individuals (50,51). Splenectomy ameliorates but does not cure the hemolytic process. There are several hexokinase genes (HK1–HK4) in humans. The HK1 gene codes for the hexokinase found in erythrocytes, and this gene maps to chromosome 10 (52).

**72.1.3.4 Phosphoglycerate Kinase Deficiency.** The inheritance of this disorder is unique among the glycolytic

enzymopathies in that it is X-linked (53,54). Biochemical variants of PGK deficiency manifest abnormal kinetics and/or enzyme instability. Several different PGK mutations have been identified (55–57). Females are mosaics with normal and PGK-deficient red cells, and there may be variable degrees of hemolysis. In males with PGK deficiency, hemolysis can be severe. Leukocyte PGK activity also is low but there is no evidence that these individuals have leukocyte dysfunction or increased infections. Of interest, however, the most severely PGK-deficient individuals with hemolysis also have neurologic abnormalities (i.e. seizures, mental retardation, aphasia, or movement disorders) (23). Deficient male infants experience apparent normal development until 3–4 years of age, when motor regression, expressive aphasia, and emotional lability become apparent. Seizures and progressive extra pyramidal disease follow late in the first decade. Most PGK variants manifest both hemolysis and neurologic disease (PGK-Uppsala, PGK-Tokyo, PGK-Matsue, PGK-Michigan); however, there are exceptions. PGK-Shizuoka is characterized by hemolysis and muscle disease, while PGK-San Francisco has only hemolysis without other symptoms (56).

**72.1.3.5 Phosphofructokinase Deficiency.** Phosphofructokinase (PFK) in RBCs is a tetrameric protein made up of two types of subunits: muscle or M type subunits, and liver or L type subunits (58). The M type subunit is encoded by a gene on chromosome 1 (56). The L type PFK deficiency subunit is encoded by a gene located on chromosome 21. The RBC contains equal amounts of M and L subtypes and all possible tetrameric variations are present ( $L_4$ ;  $L_3 M_1$ ;  $L_2 M_2$ ;  $L_1 M_3$ ;  $M_4$ ). The clinical manifestations of this enzyme deficiency relate to the specific type of structural enzyme abnormality in PFK. In all cases associated with hemolysis, red cells show only partial PFK deficiency, with about 50% normal enzyme activity, although there is a profound enzyme deficiency in muscle and this is associated with a severe myopathy (59). In these cases of PFK deficiency, RBCs lack M subunits although the L subunits are present (60). Hemolysis is thought to occur because tetramers of the L type PFK subunits are unstable and their enzymatic function is inhibited under normal intracellular conditions. Of interest, a second syndrome is recognized in which the degree of PFK deficiency is similar but there is little if any hemolysis and no muscle disease. This latter condition is due to a deficiency in the L subunits.

**72.1.3.6 Aldolase Deficiency.** Aldolase catalyzes the conversion of fructose-1,6-diphosphate to dihydroxyacetone and glyceraldehyde-3-phosphate. It is a tetrameric protein and three tissue isozymes (A, B, and C) have been identified. Type A aldolase, the main isozyme in RBCs and muscle has been characterized and cloned. Aldolase deficiency as a cause of hemolytic anemia is very rare, and has been identified in only four kindred. The first case was documented in a child whose parents were first cousins. In addition to mild hemolytic anemia, the child had

hepatomegaly associated with increased glycogen deposition and psychomotor retardation (61). A second report of aldolase deficiency, in a Japanese family, described more severe hemolytic anemia (hemoglobin 6 g/dl; 7–8% reticulocytes) without attendant hepatomegaly or developmental delay (62,63). In a third case, a 4½-year-old boy in Germany was identified with aldolase deficiency (64). He had a history of neonatal jaundice, recurrent episodes of jaundice beyond the newborn period, and anemia requiring red cell transfusions in the first year of life. In addition, however, he had a myopathy characterized by severe muscle weakness, exercise intolerance, and laboratory evidence of rhabdomyolysis in association with fever and an upper respiratory infection. In a fourth reported case, a young girl of Sicilian extraction had a transfusion-dependent hemolytic anemia requiring splenectomy at 40 months of age (65). She also had a myopathy with recurrent and progressive episodes of rhabdomyolysis. She died because of hyperkalemia and rhabdomyolysis during a febrile illness associated with gastrointestinal (GI) hemorrhage at 54 months of age. Molecular analysis in each of these cases has identified several different missense or nonsense mutations, each resulting in a thermolabile unstable enzyme (64–67). The mechanism of hemolysis in these cases is uncertain. Deficient red cells accumulate proximal glycolytic intermediates, especially fructose-1,6-diphosphate.

**72.1.3.7 Triose Phosphate Isomerase Deficiency.** Triose phosphate isomerase (TPI) deficiency is encoded by a gene on chromosome 12. Only one isozyme of TPI is produced and, thus, enzyme deficiency is shared by several tissues. At least 30 cases of TPI deficiency with hemolytic anemia have been described. Several different point mutations in the TPI gene have been identified (68,69). All clinically affected patients have been homozygotes or, less commonly, compound heterozygotes. Of the known mutations, one in particular accounts for the molecular defect in almost all studied families with TPI deficiency. This variant is due to a mutation at codon 104 (GAG→GAC), which results in a single amino acid substitution (glu→asp) and an unstable enzyme (70).

The most unique feature of this enzymopathy is an associated severe neurologic disorder characterized by spasticity, motor retardation, and hypotonia. These neurologic abnormalities usually become manifest after 6 months of age, and most affected patients die before they are 5 years old. An interesting report of TPI deficiency with chronic hemolytic anemia has been described in a 13-year-old boy and his 23-year-old brother. Noteworthy was the observation that the 13-year-old boy had hyperkinetic tortion dyskinesia, but his 23-year-old brother had no neurological abnormalities. It is interesting to note that the frequency of the heterozygous state for TPI deficiency is relatively high (0.1–0.5% in whites, 5.5% in blacks) (71). The rare occurrences of homozygous TPI deficiency may reflect incompatibility with fetal life.

Prenatal diagnosis of TPI deficiency initially relied on biochemical analyses of cultured fetal amniocytes, and in

one published report this was successful (72). Now, the large number of cases associated with the codon 104 mutation has allowed the use of chorionic villus biopsy samples and molecular techniques for prenatal diagnosis (73).

## 72.2 PURINE AND PYRIMIDINE ABNORMALITIES ASSOCIATED WITH HEMOLYSIS

Many of the enzymes utilized for purine and pyrimidine synthesis are present in erythrocytes (Figure 72-1), although mature RBCs do not synthesize DNA and are incapable of *de novo* purine or pyrimidine synthesis. Abnormal activity of these erythrocyte enzymes, however, often is observed with inborn errors of metabolism.

### 72.2.1 Pyrimidine 5'Nucleotidase Deficiency

Pyrimidine 5'nucleotidase (P5'N) is an enzyme that degrades pyrimidine nucleotides to inorganic phosphate and the corresponding pyrimidine nucleoside (74). Deficiency of P5'N is now recognized as one of the more common hereditary enzymopathies associated with hemolysis (75–77). It is found throughout the world, although there may be a predilection for individuals of Mediterranean and African ancestry. It is generally agreed that P5'N deficiency is inherited as an autosomal recessive disorder. Family members are hematologically normal, although they manifest reduced P5'N activity consistent with biochemical heterozygosity. The disorder is characterized by mild to moderate anemia, reticulocytosis, and hyperbilirubinemia. RBC morphology is unique in that marked basophilic stippling is present. Splenomegaly usually is observed and occasionally there is hepatomegaly. There are no enzymatic abnormalities in platelets or leukocytes. The most reasonable explanation for hemolysis in P5'N deficiency is that retained aggregates of ribosomes produce direct membrane injury, akin to that observed with Heinz bodies. Basophilic stippling of RBCs is the morphologic equivalent of partially degraded ribosomes (78). The enzyme activity in affected patients is less than 5% of that detected in normal RBCs of comparable age. Treatment for this disorder is supportive and RBC transfusions are required rarely. Splenectomy is not effective. However, since cholelithiasis is common, patients should have periodic ultrasound examinations for gallstones.

Of interest, the normal P5'N enzyme is readily inactivated by heavy metals such as lead, and it has been proposed that the basophilic stippling in lead poisoning is secondary to acquired P5'N deficiency (79). *In vitro* studies support the hypothesis that a consequence of mild lead intoxication is acquired P5'N inhibition (80). Moreover, cases of acute lead poisoning associated with hemolytic anemia are associated with basophilic stippling, decreased P5'N activity, and increased pyrimidine nucleotides, all characteristics of hereditary P5'N deficiency.

### 72.2.2 Adenosine Deaminase Excess

In contrast to other enzyme disorders that cause hemolysis this condition is due to a 60-fold to 100-fold excess of enzyme activity. In contrast to other enzymopathies, ADA excess is inherited in an autosomal dominant pattern (74,81). This rare cause of congenital hemolytic disease has been described in several families. Clinical features include mild to moderate anemia, reticulocytosis, and hyperbilirubinemia. The increased ADA production is associated with an elevated level of structurally normal ADA mRNA; however, no specific DNA mutation has been identified. The function of this enzyme is to catalyze the irreversible deamination of adenosine to inosine, a critical step in the purine salvage pathway. In patients with increased ADA activity, erythrocyte ATP content is reduced, presumably because the high ADA activity effectively competes with other adenosine-dependent reactions. There are no distinguishing clinical, hematologic, or morphologic features to aid in the diagnosis of this disease. The specific diagnosis is confirmed by demonstrating increased ADA activity in a hemolyzate. Usually no specific therapy is indicated since most patients have very mild anemia. It is noteworthy that a much smaller increase in enzyme activity (1.5- to 4.0-fold) has been observed in Diamond–Blackfan anemia (DBA) (see later).

### 72.2.3 Adenylate Kinase Deficiency

Adenylate kinase (AK) reversibly catalyzes the interconversion of adenine nucleotides and thereby salvages adenosine monophosphate (AMP) generated in a variety of RBC reactions. Hereditary nonspherocytic hemolytic anemia has been reported in 11 families with erythrocyte AK deficiency (38,62,77,82,83). In most cases AK deficiency is associated with moderate to severe hemolytic anemia. In some cases there also is psychomotor impairment (83,84).

In one report, there was congenital hemolytic anemia and a marked reduction in erythrocyte AK activity in one patient, although the proband's brother, who was hematologically normal, also had no detectable erythrocyte AK activity (85). The significance of this observation is not known. The AK enzyme has been studied at a molecular level in almost all cases, and each family has its own unique mutation, predominantly a missense mutation.

## 72.3 HEMOLYSIS DUE TO HEREDITARY RED BLOOD CELL MEMBRANE DISORDERS

The RBC membrane structure is a bilayer of phospholipids intercalated with molecules of unesterified cholesterol and glycolipids (Figure 72-2). The phospholipids are asymmetrically organized, with the choline phospholipids (phosphatidyl choline and sphingomyelin) primarily

**FIGURE 72-2** Structure of the RBC membrane.

on the outside half of the bilayer and the amino phospholipids (phosphatidyl ethanolamine and phosphatidyl serine) on the inside half. The membrane also contains proteins that are asymmetrically organized. All the glycoproteins are exposed on the outer membrane surface, and these are red cell antigens and receptors (i.e. glycophorins) or transport proteins (i.e. the anion transport channel). These integral membrane proteins penetrate or span the lipid bilayer, interact with the hydrophobic lipid core, and are tightly bound to the membrane. A separate protein network forms the membrane cytoskeleton that interacts with both the integral membrane proteins and the lipid bilayer. This cytoskeleton is composed of spectrin, ankyrin, protein 4.1, pallidin (protein 4.2), and actin. The biochemical and genetic characteristics of these RBC membrane proteins are depicted in [Table 72-4](#). Spectrin is made up of  $\alpha\beta$  heterodimers, which, at the head end, interact with other spectrin  $\alpha\beta$  dimers to form heterotetramers ( $\alpha\beta$ )<sub>2</sub>. These spectrin tetramers are the major structural subunits of the membrane skeleton. At the distal end, spectrin tetramers interact with protein 3 (the anion exchange channel) via ankyrin, and this interaction is important for attachment of the cytoskeleton to the membrane. Also at the distal end, spectrin tetramers interact with actin via protein 4.1. In addition, there are other membrane protein interactions not directly involving spectrin. The horizontal protein interactions, mainly the interactions of spectrin dimers, are responsible for the lateral deformability of the cytoskeleton. Thus, these protein interactions are responsible for the overall stability of the membrane, thereby allowing the RBC to be deformable during its life span within the circulation. Hereditary RBC membrane disorders are due to alterations in the quantity, quality, or both of these individual proteins and their interactions with each other. HS is due to an uncoupling of the cytoskeleton from the lipid bilayer, thereby leading to membrane instability with loss of lipids and some integral membrane proteins. Hereditary elliptocytosis (HE) disorders are due to defects in

spectrin dimer interactions, thereby leading to disruption of the skeletal lattice and RBC fragmentation. Several excellent reviews of the molecular advances in these diseases are available ([86–88](#)).

### 72.3.1 Hereditary Spherocytosis

**72.3.1.1 Prevalence and Demography.** This is the most common hereditary hemolytic anemia occurring in Caucasians ([89–91](#)). Approximately one per 5000 individuals of Northern European extraction is affected. It also occurs in other ethnic groups, but at a much lower frequency.

**72.3.1.2 Genetics.** In at least 75% of cases, HS is an autosomal dominant disorder and one parent (and often other family members) usually has the disease. The remaining 25% of HS cases are thought to be autosomal dominant disorders with decreased penetrance, autosomal recessive disorders (supported by the reports of families in which apparently normal parents have had more than one affected child), or new mutations (supported by the fact that approximately 50% of the offspring of individuals with sporadic HS also have the disease).

**72.3.1.3 Biochemistry and Pathophysiology.** The basic defect in HS is due to an alteration in the RBC cytoskeleton, which normally stabilizes membrane lipids and integral proteins. Most cases are related to spectrin deficiency, and the degree of spectrin deficiency correlates closely with the severity of disease. Mutations of  $\alpha$  spectrin are associated with recessive HS while mutations of  $\beta$  spectrin occur in families with autosomal dominant HS. Mutations in the ankyrin gene lead to secondary defects in spectrin assembly and thereby decreased RBC spectrin content. Genetic defects in band 3 or pallidin also lead to abnormal spectrin interactions and the clinical picture of HS. Individuals with autosomal recessive HS have only 40–50% the normal amount of spectrin (relative to band protein 3), while red cell spectrin levels range from 60 to 80% of normal in the autosomal dominant form of

**TABLE 72-4 Characteristics of Red Blood Cell Membrane Cytoskeletal Proteins**

SDS-Page Band	Protein Involvement Localization Anemias	MW (kDa) in Hemolytic	Total (%)	Chromosome
1	$\alpha$ -Spectrin HE, HS	240	16	1 q22–q23
2	$\beta$ -Spectrin HE, HS	220	14	14 q23–q24.2

HS, hereditary spherocytosis; HE, hereditary elliptocytosis; HSt, hereditary stomatocytosis; G3PD, glyceraldehyde-3-phosphate. Data from Glader (2004), modified from Palek and Jarolim (1995).

HS. Numerous mutations have been observed in each of the genes involved in membrane protein synthesis (Table 72-4). Most of these mutations are private in that they are unique to a given family, and thus not useful for genetic screening.

The major physiologic abnormality in HS is RBC membrane instability. Erythrocytes exit from the bone marrow as normal biconcave disks, but the intrinsic membrane instability leads to loss of lipids because the spectrin-deficient cytoskeleton is unable to provide adequate support for the lipid bilayer (Figure 72-3). The loss of membrane surface area transforms red cells from biconcave discs to spherocytes. An important physiologic consequence of this is that cellular deformability of spherocytes is decreased and this leads to their destruction by splenic macrophages.

**72.3.1.4 Clinical Features.** In most cases, the degree of anemia in HS is minimal and patients have no major limitations. Jaundice is common in the newborn period, and 30–50% of adults with HS have a history of jaundice during the first week of life. The magnitude of hyperbilirubinemia sometimes may be such as to require exchange transfusion. Beyond the neonatal period jaundice is rarely intense. An increase in scleral icterus and a darker urine color commonly are seen in children with nonspecific viral infections. From a clinical perspective, it has been useful to classify HS according to the severity of disease (92–94).

*Moderate HS*—accounts for 60–75% of cases; usually manifests autosomal dominant pattern of transmission, although new mutations can occur; recognized as a chronic hemolytic disorder with characteristic RBC spherocytes on the peripheral blood smear; associated with mild to moderate anemia, modest splenomegaly, and intermittent jaundice.

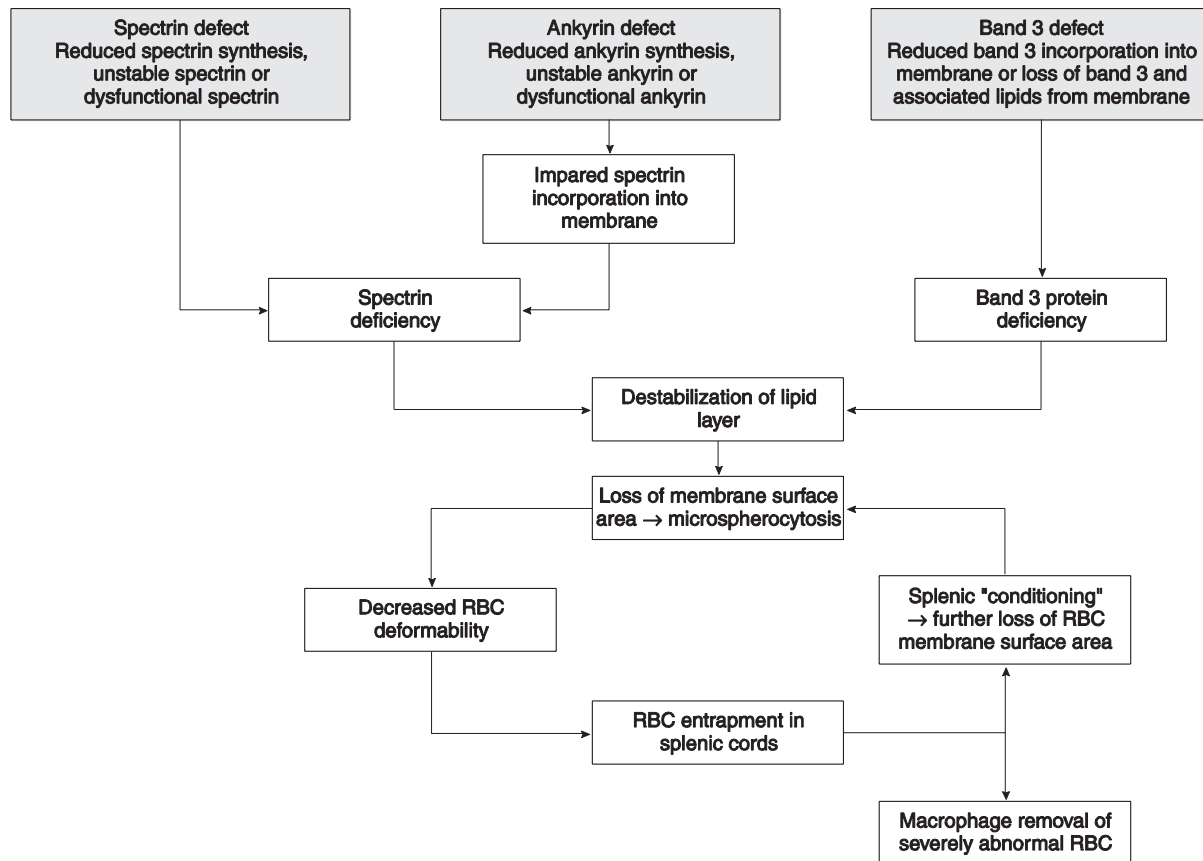

*Mild HS*—accounts for 20–30% of cases; autosomal dominant inheritance; generally no anemia because the bone marrow is able to compensate for increased RBC destruction; little or no splenomegaly; few spherocytes on blood smear; usually asymptomatic and often not diagnosed until later in life during a hemolytic or aplastic episode triggered by infection.

*Severe HS*—accounts for 5% of cases; almost always a recessive pattern of inheritance; characterized by severe hemolytic anemia, requiring RBC transfusions.

In addition to the previous categories there exists the HS silent carrier state in families with autosomal recessive HS. In most of these cases, the parents of an affected patient have no signs of HS or only a mild increase in the reticulocyte count.

The two major complications seen in HS are episodic worsening of anemia and the development of gallstones. Exacerbations of anemia occur in almost all HS patients. Often this is due to increased hemolysis associated with nonspecific viral infections. Hypoplastic crises due to human parvovirus infection also occur, and can be a medical emergency because of the rapid decrease in hemoglobin, but crises do not occur more than once. Cholelithiasis is common in HS just as in other chronic hemolytic disorders. Bilirubin gallstones are uncommon before 5 years of age, but the incidence increases markedly with age, and are present in 40–80% of adults who have not been splenectomized. In patients with mild HS, cholelithiasis may be the first sign of an underlying red cell disorder. It is of interest that the coinheritance of the gene for Gilbert syndrome is associated with a five-fold increase in gallstone formation (95).

**72.3.1.5 Laboratory Features.** Characteristics of HS are mild to moderate anemia, reticulocytosis, and the presence of spherocytes (RBC lacking central pallor) in

**FIGURE 72-3** The pathophysiology of hereditary spherocytosis is a consequence of spectrin, ankyrin, or band 3 abnormalities, which lead to membrane instability, loss of lipid microvesicles, decreased red cell surface area, reduced cellular deformability, and stagnation of RBC in the splenic cords. (From Glader, B. E. *Wintrobe's Clinical Hematology*; Lippincott Williams and Wilkins: Philadelphia, 2004.)

the peripheral smear. The loss of membrane surface area is associated with RBC dehydration as manifested by an elevated mean corpuscular hemoglobin concentration (MCHC) greater than 35%. The commonly used test for diagnosing HS is the incubated osmotic fragility test, which indirectly detects spherocytes by measuring RBC lysis in sodium chloride solutions of varying concentrations. A newer test employs flow cytometry to measure eosin-5-maleimide (EMA) binding to erythrocytes, reflecting relative amounts of band 3 and Rh-related proteins (96). The purported advantage of the EMA binding flow test is that there are no false-positive results with immune-mediated or non-membrane-associated hemolytic disease. However, a disadvantage of the EMA procedure is that the test is nonspecific, also detecting other erythrocyte abnormalities, especially those associated with abnormal band 3, including congenital dyserythropoietic anemia (CDA), and abnormalities of erythrocyte hydration.

**72.3.1.6 Therapy.** Definitive therapy for HS is splenectomy, which removes the site of RBC destruction (93). Following splenectomy, the hemoglobin concentration almost always increases, reticulocytes decrease, bilirubin levels return to normal, and RBCs have a relatively normal life span. The one exception to this favorable response to splenectomy is seen in patients with the

autosomal recessive form of HS, who may continue to hemolyze. Most hematologists now recommend that HS patients with moderate degrees of hemolysis have a splenectomy after 5–10 years of age. If patients have not developed gallstones before splenectomy, it is unlikely they will develop bilirubin stones at a later date. Splenectomy is not indicated before age 5 years, since a functioning spleen is important in young children for protection against infections due to encapsulated bacteria. Children are given pneumococcal vaccine before splenectomy and placed on prophylactic penicillin therapy for at least 2 years following surgery.

### 72.3.2 Hereditary Elliptocytosis

This is an autosomal dominant disorder that occurs in one per 2000–4000 people in all racial and ethnic groups, but in the United States it appears to be much more common among African-Americans (86,90,91). In areas where malaria is endemic, HE is considerably more frequent, having a prevalence of 0.6% in equatorial Africa. Like HS, HE is transmitted as an autosomal dominant trait and in most cases is associated with no or minimal clinical abnormalities. Spectrin abnormalities are found in the vast majority of patients with HE, and almost all these are due to  $\alpha$ -spectrin mutations (86,90).

Most of the  $\alpha$ -spectrin mutations result in abnormal spectrin dimer–dimer interaction. Three distinct HE syndromes are summarized here.

Common HE is a dominantly inherited condition characterized by many elliptocytes in the peripheral blood smear. The clinical severity of common HE is extremely variable, ranging from an asymptomatic condition (80%), to a moderate hemolytic anemia (20%). It is due to the presence of at least one  $\alpha$  spectrin mutation. In those cases associated with hemolysis, it is now recognized that a second mutation is present that allows expression of the variant  $\alpha$  spectrin (97). Individuals with common HE usually are discovered accidentally when elliptocytes are identified during routine evaluation of the peripheral blood film. These people usually are not anemic, reticulocytes are normal or only slightly elevated, and there is no splenomegaly. However, the peripheral blood smear is striking, containing 15–100% elliptocytes. In the minority of common HE cases associated with hemolysis, the peripheral blood smear reveals numerous poikilocytes as well as elliptocytes, the spleen may be enlarged, and gallstones occur with increased frequency.

HE with infantile poikilocytosis is a clinical manifestation of HE that occurs almost exclusively in black families. Affected young infants have moderately severe hemolytic anemia and hyperbilirubinemia in the newborn period, the latter often-necessitating exchange transfusion (98). The blood smear is characterized by marked red cell fragmentation and poikilocytosis in addition to elliptocytosis. Beyond the newborn period hemolysis gradually lessens, and by 6–12 months of age the clinical and hematologic features convert to those of mild HE with the disappearance of the bizarre RBC forms and the emergence of normal elliptocytes.

Homozygous (doubly heterozygous) HE is associated with a moderate to severe hemolytic anemia due to homozygosity or compound heterozygosity for two common  $\alpha$ -spectrin mutations. Morphological characteristics include marked poikilocytosis, microelliptocytosis, and red cell fragmentation. In many cases both parents have nonhemolytic HE, or since many individuals with a single  $\alpha$ -spectrin mutation are asymptomatic, there may be no parental anemia or RBC abnormalities. These patients also have enlarged spleens, and usually benefit from splenectomy. In contrast to HS, however, the response to splenectomy usually is incomplete and hemolysis persists.

Hereditary pyropoikilocytosis (HPP) is an unusual and severe recessively inherited hemolytic anemia, characterized by red cell fragments, microspherocytes, and poikilocytes seen on the peripheral smear. HPP is the result of a double heterozygous state for an  $\alpha$ -spectrin mutation and a defect involving spectrin synthesis. Just as in other hemolytic variants of HE, spectrin dimers are increased relative to tetrameric spectrin, but the total spectrin content also is decreased (99). Most patients

with this interesting variant are black. Moreover, at least one parent or sibling invariably has a milder form of HE. Splenectomy is followed by an increase in hemoglobin concentration and a decrease in reticulocytes. Most impressive are changes in red cell morphology, which include extreme poikilocytosis, microspherocytosis, microelliptocytosis, membrane budding, and cell fragments. The mean cell volume (MCV) may be extremely low (30–50fl). The MCHC is normal. The osmotic fragility is increased.

### 72.3.3 Hereditary Stomatocytic Disorders

Stomatocytes are erythrocytes with a central slit or stoma instead of a circular area of pallor when examined on dried smears; they are uniconcave rather than biconcave, giving them a bowl-like appearance. A few stomatocytes may be observed in blood smears prepared from normal individuals, as well as from patients with acute alcoholism and hepatobiliary disease. Large numbers of stomatocytes are associated with very rare hereditary disorders of red cell cation permeability leading to increased or decreased red cell water content (100–102). It is important to recognize these disorders since venous thrombosis and pulmonary embolism are complications of splenectomy and thus this procedure is contraindicated in these conditions.(103)

### 72.3.4 Congenital Bone Marrow Failure Syndromes

**72.3.4.1 Diamond–Blackfan Anemia (Congenital Hypoplastic Anemia).** This congenital red cell aplastic anemia was first recognized 50 years ago (104,105). The anemia is not due to inadequate erythropoietin (EPO) production, since circulating EPO levels actually are elevated in DBA patients. Rather, it is due to an intrinsic defect of erythroid progenitors resulting in impaired erythroid production. Under in vitro conditions that stimulate normal differentiation erythroblast growth, little or no colony formation is seen when DBA marrow cells are studied, and there is evidence of increased apoptosis. (106).

This is a relatively rare disorder, although several hundred individuals have been identified in the medical literature, and the number of recognized persons now is increasing with the recent establishment of registries in Europe and North America (107–110). Several excellent reviews of this disorder are available (111–113). It is characterized by a lifelong anemia that usually presents in the first 2–3 months of life, and over 90% of patients are diagnosed within the first year of life. It occurs equally in both sexes and has been identified in all ethnic groups, although the majority of reported cases have been in whites. Approximately 35% of affected children manifest one or more congenital abnormalities (112). The most common abnormality is short stature.

Also common are thumb abnormalities including triphalangeal thumbs, bifid thumbs and hypoplastic thumbs. A short webbed neck, cleft palate, high-arched palate, congenital heart disease, hypertelorism, strabismus, and structural abnormalities of the kidney are other stigmata frequently encountered. It is noteworthy that many of these congenital abnormalities also are found in Fanconi aplastic anemia (see later discussion), but in DBA only RBC production is impaired and there is no evidence of increased chromosome fragility.

Although most DBA cases are sporadic (75%), it generally is thought that this is a genetic disorder since 10–15% of cases occur in kindred that have had more than one affected family member (109). Both autosomal dominant and autosomal recessive modes of inheritance have been postulated. It has been observed in cousins, identical twins, full siblings, and, in several instances, in half-siblings where the father or mother has had a different mate. It also has been observed to occur in a parent and child, and several large kindreds with autosomal dominant transmission over three generations have been observed (114,115).

The observation of DBA in a girl with a balanced reciprocal X:19 translocation was the initial finding leading to the identification of a specific gene (116). Further studies localized 19q13 as the putative site for at least one DBA gene, now known to be a gene (RPS19) for directing the production of a ribosomal protein. Mutations in RPS19 occur in 25% of unrelated DBA patients. It is now recognized that DBA is a disorder of ribosome biogenesis (117–119). Nine ribosomal protein gene mutations have been identified to date and these account for 50% of recognized DBA cases (120).

The diagnosis of DBA is suggested by anemia with reticulocytopenia presenting in infancy. The bone marrow reveals decreased erythroid precursors while myelopoiesis and megakaryopoiesis are normal. Circulating RBCs have many fetal-like characteristics and these abnormal features persist throughout life, independent of the patient's therapy or clinical state. These RBC are macrocytic relative to the patient's age and the fetal hemoglobin concentration often is elevated. A majority of DBA patients (greater than 75%) have increased erythroid activity of adenosine deaminase. Elevated RBC ADA activity also has been observed in some healthy relatives of DBA individuals (121). It has been observed that this biochemical abnormality in family members cosegregates with the DBA gene region on chromosome 19q13. Taken together, these findings suggest there probably is a silent carrier state for DBA (112,122).

Corticosteroids correct the anemia in many DBA patients (112,123). In some cases, trivial prednisone doses are necessary to sustain a remission, while in other patients remission is maintained without steroids. However, the clinical course can change abruptly at any time. Those who fail steroids rarely respond to other pharmacologic agents and most require RBC transfusions.

Consequently, iron overload is a serious problem in transfusion-dependent DBA patients and lifelong chelation therapy is necessary. For this reason, just as for transfusion-dependent children with various thalassemia syndromes, BMT from a human leukocyte antigen (HLA) compatible sibling is considered as an alternative therapy for this disorder. This approach generally is reserved for DBA children who demonstrate an absolute dependence on RBC transfusions for 4–5 years. Several patients now have been transplanted with a successful outcome (63,107). A concern in evaluating HLA-matched family members as possible bone marrow donors is the problem of identifying those who may be silent carriers. This requires assessing donor erythrocyte ADA activity and, if available, testing for known DBA mutations. The use of unrelated donors for stem cell transplants in DBA has been discouraged because of the poor outcomes (112). However, the recent availability of new transplant conditioning drugs resulting in markedly increased survival rates, may lead to a larger use of unrelated donors for certain DBA patients (123).

The prognosis for the majority of DBA patients who respond to steroids is generally quite good. Affected women are known to have become pregnant and delivered normal infants, although pregnancy occasionally exacerbates the magnitude of anemia. Of concern, however, acute leukemia, myelodysplastic syndrome, and other malignancies (especially osteosarcoma) may be delayed complications of this disorder (112). In view of the rarity of DBA, the number of leukemia cases described to date suggests this is more than a chance event.

**72.3.4.2 Fanconi Anemia (Constitutional Hypoplastic Anemia).** Aplastic anemia is characterized by anemia, thrombocytopenia, and leukopenia with reduced or absent hemopoietic precursor cells in the bone marrow. Most commonly, this is an acquired disorder occurring in previously healthy individuals. In the majority of cases it is due to an immunologic assault on marrow stem cells. There also are constitutional or hereditary forms of aplastic anemia, the most common of which is Fanconi anemia (FA) (120,124–126). This is an autosomal recessive disorder with a heterozygote frequency of 1 in 300. The disorder occurs in all races and ethnic groups.

In addition to the hematologic problems, FA is associated with a variety of physical abnormalities for a majority of children (127). Common findings include skin hyperpigmentation, increased cafe-au-lait spots or both (62%); short stature (59%); skeletal abnormalities, particularly of the thumb (48%); hypogonadism in males (42%); renal anomalies (24%); microcephaly or micrognathia (26%); low birth weight (14%); retardation (13%); ear abnormalities, with or without deafness (10%) and, rarely, congenital heart disease and GI tract abnormalities.

The onset of pancytopenia usually occurs during the first decade of life, although it may appear later. The clinical manifestations begin insidiously with

thrombocytopenia, leukopenia or both that evolves into mild pancytopenia, and gradually becomes more severe over months to years. The anemia typically is macrocytic and the fetal hemoglobin concentration is increased.

A characteristic feature of FA is increased chromosomal breaks in cultured skin fibroblasts and in peripheral blood lymphocytes stimulated in vitro with clastogenic drugs. Cells from FA patients are particularly sensitive to certain crosslinking agents that damage DNA and produce chromosomal abnormalities. This particular sensitivity is the basis of the current diagnostic test, which employs diepoxybutane (DEB) as the clastogenic agent to induce chromosomal breakage in peripheral blood lymphocytes (128). The DEB breakage studies do not discriminate FA heterozygotes from the normal population. The test also does not distinguish severe and mildly affected FA patients. Since approximately one-third of all FA patients have no congenital abnormalities, a DEB-chromosomal breakage study should be done on any new patient thought to have acquired aplastic anemia. Moreover, since FA patients have a predilection for developing leukemia (see later discussion) any new acute myeloid leukemia (AML) patient should be screened because acute leukemia may be the first manifestation of FA. This is important because FA patients have a very poor tolerance of standard antileukemia chemotherapy.

There are many theories about the pathophysiology of FA, including increased sensitivity to oxygen free radicals and defects in DNA repair; however, the precise reason for this increased susceptibility of DNA injury remains unknown (124,129). It is of major significance that the increased chromosomal breakage induced by alkylating agents is corrected to normal when FA fibroblasts are fused in vitro with normal cells. Moreover, since fusion of cells between different FA patients occasionally corrects the breakage sensitivity in hybrid cells, this suggests a different cause of increased chromosomal fragility in each of these cells. These observations now have resulted in the characterization of 11 different FA complementation groups and 13 genes have been characterized FANC-A, B, C, D1, D2, E, F, G, I, J, L, M and N (120). FANC-A accounts for 65% of FA cases, FANC-C 12%, FANC-G 12% cent, and the other known genes responsible for 11% of cases. An important function of FA proteins is to maintain chromosomal stability, but it is not clear how this occurs.

In a majority of children with FA there is a beneficial response to androgen therapy and most children who respond require only small doses to maintain a remission. After a few years, refractoriness to androgens develops and most patients ultimately succumb to progressive bone marrow failure and its complications. In about 20% of cases, patients develop cancer, and in some older patients this may be the initial presentation without a preceding pancytopenic phase. In most cases the malignancies are due to myelodysplasia or acute myelogenous leukemia. A smaller number, 5%, develop

solid tumors (GI tract, liver, and gynecologic). These malignancies tend to occur in older FA patients, more commonly female, sometimes without an antecedent history of aplastic anemia.

The most appropriate therapy for an FA patient with significant aplasia is BMT from an HLA compatible sibling. The best time to perform this procedure is not clear but, in order to avoid HLA sensitization, it probably should be done before platelet transfusion therapy is needed. Since this is an autosomal recessive disorder, it is critical to check potential stem cell donors to determine whether they have FA. This testing must include DEB chromosome breakage studies and chromosome analysis. A unique complication of transplantation in FA patients is severe skin and GI toxicity due to the conditioning drugs (i.e. cyclophosphamide), presumably a consequence of chromosomal fragility in these other tissues. The overall survival from marrow transplantation using HLA-matched related donors approaches 75% at 5 years, while the outcome for matched unrelated donors has been very poor. However, with the development of new transplant conditioning regimens, the outcomes using unrelated donors have improved significantly (130,131). Utilizing preimplantation genetic diagnosis it is possible to select an embryo that is both HLA compatible and does not have FA (132). The decisions regarding stem cell transplant for FA, and when to undergo the procedure, continue to be defined as new data appear.

A long-term complication after successful hematopoietic engraftment is the later occurrence of malignancies; in one report there was a 24% projected incidence of having cancer 8 years after BMT. This increase reflects the fact that correction of the hematologic problem leads to longer survival, but genetic instability in other tissues allows for the expression of cancer. Gene therapy in the future may be used for this disorder and published studies indicate it is possible to insert the cloned FANC-C and FANC-A gene into hematopoietic FA stem cells and provide protection against clastogenic agents (133).

## 72.4 MEGALOBlastic ANEMIAS

Megaloblastic anemias are characterized by abnormal differentiation of bone marrow erythroblasts and ineffective erythropoiesis. This results in a macrocytic anemia and the peripheral blood smear typically manifests hypersegmented neutrophils with many having more than five lobes. In all cases, megaloblastic erythropoiesis is a consequence of impaired DNA synthesis. Most genetic causes of megaloblastic anemia are due to abnormalities of vitamin B<sub>12</sub> metabolism (134).

Dietary vitamin B<sub>12</sub> (cobalamin), found in eggs, milk products, meats, and vegetables, is released from complex food forms by proteolytic enzymes in the stomach. Once in the duodenum, vitamin B<sub>12</sub> binds to intrinsic factor (IF), a protein secreted by gastric parietal cells. Subsequently, the IF-B<sub>12</sub> complex binds to specific

receptors in the distal part of the ileum, IF is split off, and B<sub>12</sub> is transported into intestinal cells. Next, cobalamin binds to a transport protein, transcobalamin II (TC-II), which carries the B<sub>12</sub> to the liver, bone marrow, and other tissue storage sites. Serum also contains two other B<sub>12</sub> binding proteins, transcobalamin I and III (TC-I and TC-III). The latter two forms of transcobalamin have no specific transport role but are known to reflect vitamin B<sub>12</sub> tissue stores. In fact, almost all B<sub>12</sub> in plasma is bound to TC-I and TC-III and thus the measurement of serum B<sub>12</sub> concentration reflects the storage of this vitamin. One important metabolic function known to be impaired in human B<sub>12</sub> deficiency is methylmalonyl-CoA, an important reaction in propionic acid metabolism. When this reaction is impaired, there is both methylmalonic acidemia and methylmalonic aciduria, and testing for the latter is a good screening test for B<sub>12</sub> deficiency. A second important reaction requiring B<sub>12</sub> is homocysteine:methyltetrahydrofolate methyltransferase. In this reaction a methyl group from methyltetrahydrofolate is transferred to homocysteine with the formation of methionine and tetrahydrofolate. The latter is a required cofactor for thymidine synthesis, partially explaining why DNA synthesis is defective in vitamin B<sub>12</sub> deficiency. Megaloblastic anemia due to vitamin B<sub>12</sub> deficiency can occur because of an abnormality in any one of the steps in B<sub>12</sub> absorption, transport, or metabolism. Acquired causes include loss of IF following gastrectomy or loss of absorptive sites after extensive ileal resection, tapeworm infestation, or intestinal bacterial overgrowth (from broad spectrum antibiotic therapy). The remainder of this section focuses on those megaloblastic anemia conditions due to B<sub>12</sub> deficiency that are considered genetic disorders.

### 72.4.1 Classical Pernicious Anemia

This disorder is the most common form of B<sub>12</sub> deficiency and usually occurs in middle-aged and elderly adults. It is characterized by macrocytic anemia and neurologic disease. The neurologic problems include decreased vibratory and position sensation of the lower extremities, paresthesias, dementia, and/or depression. The cause of pernicious anemia (PA) is impaired IF production and is associated with gastric atrophy, achlorhydria, and antibodies to both gastric parietal cells and IF. The disorder traditionally has been diagnosed by low serum vitamin B<sub>12</sub> levels and an abnormal Schilling test that measures B<sub>12</sub> absorption with and without added IF. The Schilling test is not available nowadays. Currently, the most direct functional evidence of decreased cobalamin is suggested by increased levels of cobalamin intermediates, homocysteine and methylmalonic acid. There may be an ethnic predisposition to develop PA for Northern Europeans, in particular Scandinavians; however, the disorder is known to occur worldwide in many different ethnic groups. It is not clear that this is a genetic disease,

although 20% of PA patients also have an affected relative with the same disease.

### 72.4.2 Congenital Intrinsic Factor Deficiency

This rare megaloblastic anemia is first recognized between 1 and 4 years of age. It is due to a congenital absence of functional IF (135). There are none of the other gastric abnormalities or other antibody features of classic PA. Infants may also manifest failure to thrive and, occasionally, abnormal neurologic findings. The occurrence of multiple affected siblings suggests autosomal recessive inheritance; no abnormalities have been found in parents or other relatives. Reports indicate that hereditary cobalamin deficiency is due to mutations in the gastric IF gene (GIF) (136). Treatment is parenteral vitamin B<sub>12</sub> for life.

### 72.4.3 Impaired Vitamin B<sub>12</sub> Absorption (Imerslund–Grasbeck Syndrome)

Imerslund (137) and Grasbeck (138) first described children with familial malabsorption of vitamin B<sub>12</sub> due to impaired ileal uptake of cobalamin, presumably due to an abnormality of the receptor for B<sub>12</sub> absorption. There are no gastric abnormalities and IF production is normal. This disorder is now referred to as Imerslund–Grasbeck syndrome (IGS) (139). This is a relatively rare condition, found particularly in Finland, Norway, and the eastern Mediterranean region. It is known to be transmitted as an autosomal recessive disorder and most children show marked failure to thrive in the first 2 years of life. Characteristically there is megaloblastic anemia with low serum B<sub>12</sub> levels. Of interest, however, mild proteinuria also is present in many patients. It is now recognized that this disorder is due to mutations in the cubulin (CUB) or amnionless (AMN) genes (140,141). The protein products of these two genes form a heterodimer called cubam that is responsible for the internalization of the IF-cobalamin complex (142). Therapy is parenteral B<sub>12</sub> given every 2–3 months for life.

### 72.4.4 Transcobalamin II Deficiency

This autosomal recessive disorder is due to a deficiency of the major transport protein for vitamin B<sub>12</sub>. However, serum vitamin B<sub>12</sub> levels are normal since TC-I and TC-III are not affected. Approximately 30 cases of transcobalamin II deficiency have been reported. In rare instances, TC-II may be detected immunologically, although it demonstrates defective binding to vitamin B<sub>12</sub>. Generally, this disorder manifests itself in the first weeks of life. Characteristically there is a failure to thrive, diarrhea, vomiting, glossitis, neurologic abnormalities, and megaloblastic anemia. The diagnosis of this disorder is suggested by the presence of severe megaloblastic anemia with normal serum B<sub>12</sub> and folate levels with no evidence

of any other inborn errors of metabolism. The serum B<sub>12</sub> levels must be kept high to utilize cobalamin. Hence, the therapy for this disorder is large parenteral doses of vitamin B<sub>12</sub> given twice a week for life. These frequent and large doses of cobalamin appear to overcome the transport deficiency. Most children with this disorder die if not treated in infancy.

### 72.4.5 Hereditary Orotic Aciduria

This autosomal recessive disorder usually appears in the first year of life and is characterized by growth failure, developmental retardation, megaloblastic anemia, and increased urinary excretion of orotic acid. This defect, the most common metabolic error in the *de novo* synthesis of pyrimidines, affects nucleic acid synthesis. The usual form of hereditary orotic aciduria is caused by a deficiency (in all body tissues) of both orotic phosphoribosyl transferase and orotidine-5-phosphate decarboxylase, two sequential enzymatic steps in pyrimidine nucleotide synthesis. This disorder may present as severe megaloblastic anemia with normal serum B<sub>12</sub> and no evidence of TC-II deficiency. A presumptive diagnosis is made by finding increased urinary orotic acid. Confirmation of the diagnosis, however, requires assay of the transferase and decarboxylase enzymes in the patient's erythrocytes. The heterozygous state is characterized by intermediate levels of enzyme activity in otherwise healthy individuals.

## 72.5 DYSERYTHROPOIETIC ANEMIAS

CDA refers to a class of hemolytic disorders characterized by unique morphologic abnormalities in marrow erythroblasts (multinuclearity, abnormal nuclear fragments and intrachromatin bridges between cells) (101,143–145). Clinically these disorders are characterized by variable degrees of anemia despite the fact that there is markedly increased marrow erythroid activity (i.e. ineffective erythropoiesis). CDA has been reported in newborn infants with hydrops fetalis (145–147). Three major types of CDA (types I, II, and III) have been defined.

### 72.5.1 Type I Congenital Dyserythropoietic Anemia

This is a very rare autosomal recessive disorder in which the onset of anemia and/or jaundice may be noted at any age. Affected patients can manifest slight icterus, moderate splenomegaly, and a mild to moderate macrocytic anemia. (145,148,149). The reticulocyte count is less than expected for the degree of anemia. In more than half of cases anemia is first recognized in the neonatal period. A characteristic feature is RBC macrocytosis persisting beyond the newborn period with MCVs ranging between 100 and 120 fl. Peripheral RBC morphology is characterized by large poikilocytosis and ovalocytes,

similar to that seen in megaloblastic anemias. White blood cells and platelets are normal. Indirect bilirubin levels are slightly elevated, haptoglobin levels are low and transferrin may be saturated with iron (serum iron level approximates the TIBC concentration). Bone marrow aspiration reveals erythroid hyperplasia with dyserythropoietic features characterized by interchromatin bridges between cells.

In contrast to Type II CDA, there are no serologic features of this dyserythropoietic anemia (see later discussion). Treatment of this disorder has been unsuccessful with the usual hematinics, including all types of vitamins, metals, and steroids. However, some success in increasing the hemoglobin has been achieved with  $\alpha$ -interferon. Splenomegaly is common, although splenectomy has not been helpful. Gallstones have been a problem in some patients. The most important long-term complication may be hemosiderosis caused by increased intestinal absorption of iron and ineffective erythropoiesis, combined with mild hemolysis. In some cases there are associated bone abnormalities of the extremities (syndactyly of the fingers and toes, hypoplasia or absence of fingers or toes, and vertebral abnormalities resulting in scoliosis) (149).

The gene for CDA I has been mapped to chromosome 15q15.1 (150) cloned (*CDAN1*), and many mutations have been identified (151). The role of codanin-1 encoded by *CDAN1* is unknown.

### 72.5.2 Type II Congenital Dyserythropoietic Anemia

This is the most common variant of CDA and several hundred cases of this autosomal recessive disorder are recognized (152). The gene for CDA II was mapped to 20q11.2 (153) and is now known to be associated with several different mutations in *SEC23B* (154,155). Abnormalities in this gene are thought to disturb normal protein transport through membrane vesicles, and thus may account for the cellular abnormalities noted in CDA II.

Characteristic laboratory features include anemia, normal-sized RBC, a relatively low reticulocyte count for the degree of anemia, elevated bilirubin, and decreased serum haptoglobin. The magnitude of anemia in type II CDA usually is greater than that seen in type I CDA. The bone marrow reveals increased red cell precursors with many (up to 50%) abnormal late erythroblasts as manifested by binuclearity, multinuclearity, and abnormal lobulation. The original pathognomonic findings in CDA type II were serologic in that the patient's red cells would lyse in the presence of acidified serum. Unfortunately, this test, originally used to screen for paroxysmal nocturnal hemoglobinuria (PNH), is no longer available. The combination of erythroblast multinuclearity and the sensitivity of circulating RBC to lysis by acidified normal serum was the reason that type II CDA also was known by the acronym HEMPAS (hereditary erythroblastic

multinuclearity with a positive acidified serum test (156). Glycosylation of membrane proteins is impaired, and there is also an accumulation of RBC glycolipids. The cause of both of these abnormalities is thought to be a deficiency of *N*-acetylglucosaminyltransferase II, an RBC enzyme responsible for membrane protein glycosylation.

Patients with severe anemia require blood transfusions, and in these cases splenectomy is helpful as manifested by a decreased need for transfusions. Iron overload occurs from both transfusions and increased intestinal absorption (even in untransfused patients), and in some patients iron chelation therapy may be necessary. Hyperbilirubinemia and cholelithiasis are variable features, which are now known to be five times more common in CDA II patients who also have inherited the mutation for Gilbert syndrome (157).

### 72.5.3 Type III Congenital Dyserythropoietic Anemia

This is the least common CDA variant. These patients have RBC macrocytosis and a mild to moderate degree of anemia. Transfusions usually are not required, icterus is minimal, and iron overloading does not occur. In contrast to CDA I and CDA II, this disorder is inherited as an autosomal dominant defect. Bone marrow examination shows erythroid hyperplasia, with many multinucleated erythroblasts containing up to 12 nuclei. The gene for type III CDA has been mapped to 15q21 (158).

## 72.6 SIDEROBLASTIC ANEMIAS

Sideroblastic anemias are due to acquired and hereditary disorders of heme synthesis (159–161). Most commonly these are acquired disorders occurring in middle age and later life, and they can be due to drugs, alcohol, myeloproliferative disorders, or they can be idiopathic. The inherited sideroblastic anemias are rare genetic conditions presenting in childhood.

In all sideroblastic anemias, regardless of etiology, a common feature is impaired heme synthesis leading to retention of iron within mitochondria. The bone marrow aspirate characteristically demonstrates nucleated red cells with iron granules in a perinuclear distribution (i.e. aggregates of iron in mitochondria). These unusual cells, known as ringed sideroblasts, are found only in pathological states, and are distinct from the sideroblasts in the marrows of normal subjects (i.e. RBC precursors that contain diffused cytoplasmic ferritin granules).

The different types of congenital sideroblastic anemias (CSAs) are summarized (162). Three of the most common are X-linked sideroblastic anemia, Pearson syndrome and thiamine-responsive megaloblastic anemia.

### 72.6.1 X-Linked Sideroblastic Anemia

This CSA usually occurs in males, although skewed lyonization has resulted in affected females. This disorder

is due to abnormalities of the erythrocytic isozyme for 5-aminolevulinic acid synthetase (ALAS2), the rate-limiting enzyme reaction in heme synthesis. An important cofactor for ALAS is pyridoxal phosphate. The gene for the erythrocyte-specific ALAS (ALAS2) is located on the X chromosome, and almost 50 different mutations have been identified in 80 unrelated individuals. Of interest, several of these mutations occur near the binding site for pyridoxal phosphate (160,161).

The anemia in this disorder is characterized by hypochromic microcytic RBC mixed with normal red cells, thus giving an overall picture of a dimorphic population of erythrocytes. Severe anemia can be recognized in infancy or early childhood, whereas milder cases may not become apparent until early adulthood or later. Reports of elderly women with late onset of X-linked sideroblastic anemia, presumably are a consequence of acquired skewing with age (163). Patients present with pallor, icterus, moderate splenomegaly, hepatomegaly or both. The severity of the anemia varies such that some patients require no therapy while others need regular RBC transfusions. A subset of patients manifests a hematologic response to pharmacologic doses of pyridoxine. In a few severe RBC transfusion-dependent cases, BMT has been done utilizing fully matched siblings as donors (164). Iron overload as manifested by elevated serum ferritin, elevated serum iron, and increased transferrin saturation is a major complication of this disorder. In some cases where there is little or no anemia, there still may be clinical evidence of iron overload (i.e. diabetes mellitus, liver dysfunction, etc.). The coinheritance of the gene for hereditary hemochromatosis has been shown to exacerbate the iron problems associated with sideroblastic anemia (165).

### 72.6.2 Pearson Syndrome

This unique variant of CSA is characterized by the early onset of transfusion-dependent anemia, neutropenia and thrombocytopenia (161,166). In addition to the usual marrow abnormalities of sideroblastic anemia, these children also have vacuolization of RBC and myeloid precursors, and pancreatic fibrosis. The anemia is normocytic or macrocytic. It is now known that this syndrome is due to mitochondrial DNA deletions in many different tissues (167,168). In the few children who survive the hematologic consequences of this mitochondrial DNA disorder, they often later develop Kearns-Sayer syndrome, due to an identical mitochondrial DNA deletion (169).

**72.6.2.1 Thiamine-Responsive Megaloblastic Anemia.** This CSA is associated with diabetes and deafness. The characteristic hematologic findings are megaloblastic erythroid development in the marrow with ringed sideroblasts. The disorder is associated with mutations in the high-affinity thiamine transporter

gene (*SLC19A2*). Of interest the anemia can respond to pharmacologic doses of thiamine.

## 72.7 METHEMOGLOBINEMIA

Methemoglobin (MHb) is an oxidized derivative of hemoglobin in which iron (normally  $\text{Fe}^{2+}$ ) is in the oxidized or ferric ( $\text{Fe}^{3+}$ ) state. When MHb levels are increased, oxygen transport is impaired because MHb does not complex with oxygen. Under normal physiologic conditions, small amounts of hemoglobin are continually being oxidized by endogenous agents including oxygen itself (auto-oxidation). Usually, however, MHb levels are less than 1% of the total hemoglobin because RBCs contain NADH-cytochrome  $\text{b}_5$  reductase, an enzyme that catalyzes the reduction of MHb. The cardinal clinical manifestation of methemoglobinemia is cyanosis without evidence of cardiac or respiratory disease (normal physical examination, chest radiograph, electrocardiograph, and arterial  $\text{PO}_2$ ). Blood appears dark in color but, in contrast to deoxygenated blood, mixing with air does not change the color to bright red. This is the basis of a simple screening test to detect MHb: a drop of blood is placed on filter paper and then allowed to dry while the filter paper is waved in air. Blood that is not saturated with oxygen turns red, while MHb remains brown. Cyanosis is apparent at MHb levels of 1.5 g/100 ml (10% of total hemoglobin), but symptoms due to decreased oxygen transport are generally not apparent until 30–40% of hemoglobin is oxidized to MHb. Levels greater than 70% are incompatible with life. Methemoglobinemia usually is not associated with anemia, hemolysis, or other hematologic abnormalities. Two forms of methemoglobinemia are seen clinically: acquired or toxic methemoglobinemia (common), and hereditary methemoglobinemia (rare). Acquired methemoglobinemia occurs in normal individuals exposed to increased concentrations of chemicals that oxidize hemoglobin iron (certain organic nitrates, amyl nitrate, aniline derivatives, lidocaine, prilocaine, dapsone, etc.). Hereditary methemoglobinemia is due to inherited hemoglobin M disorders or deficiency of NADH-cytochrome  $\text{b}_5$  reductase.

### 72.7.1 Hemoglobin M Disorders

These are rare autosomal dominant defects due to amino acid substitutions in  $\alpha$ ,  $\beta$ , or  $\gamma$  globin chains of hemoglobin (170). As a result of these substitutions, heme iron is more stable in the ferric than the ferrous state and RBC MHb reductive capacity cannot compensate for this instability of ferrous heme. Both  $\alpha$  and  $\gamma$  globin M hemoglobins are manifest at birth. However, methemoglobinemia disappears in the first few months of life in neonates with Hgb M disorders due to  $\gamma$  globin mutations. Conversely, M hemoglobin disorders due to  $\beta$  chain mutations usually do not appear until 3–5 months of age when  $\beta$  chain synthesis predominates. Heterozygotes for hemoglobin M disorders have increased MHb levels and

some degree of cyanosis but otherwise are asymptomatic. No therapy is indicated and none is possible. The homozygous state is incompatible with life. The presence of M hemoglobins can be detected by electrophoresis of a hemolysate in which the hemoglobin is converted to MHb (by potassium ferricyanide).

### 72.7.2 NADH-Cytochrome $\text{b}_5$ Reductase Deficiency

This is an autosomal recessive disorder. Heterozygotes are asymptomatic although intermittent methemoglobinemia occurs when exposed to certain oxidant drugs. Homozygous deficient patients often have 15–40% MHb and this can increase in the presence of certain oxidants. These patients are cyanotic, but otherwise are usually asymptomatic. Three different types of hereditary NADH-cytochrome  $\text{b}_5$  reductase deficiency are recognized. Type I deficiency is limited to RBC and is manifested by methemoglobinemia only. Type II deficiency is due to a widespread enzyme deficiency and is characterized by mental retardation in addition to methemoglobinemia. Type III deficiency occurs in RBC, leukocytes and platelets, but the only clinical manifestation is methemoglobinemia. The gene for NADH-cytochrome  $\text{b}_5$  reductase is located on chromosome 22. At least 18 different NADH-cytochrome  $\text{b}_5$  reductase mutations, mostly missense, have been described in three types of enzyme deficiency (171,172).

The diagnosis of NADH-cytochrome  $\text{b}_5$  reductase deficiency is made by direct assay of the enzyme. Most individuals with this deficiency usually require no treatment. Occasionally, therapy is given for cosmetic reasons to decrease cyanosis. This is readily accomplished with daily oral administration of methylene blue or ascorbic acid. Methylene blue, the most effective of the two, will produce blue urine, but this is harmless. In NADH-MHb reductase deficient patients who are symptomatic (i.e. more than 25% MHb), intravenous methylene blue (4 mg/kg as a 1% solution) can be given for prompt relief.

Erythrocytes contain a second enzyme, NADPH-MHb reductase, which by itself is unable to reduce MHb and individuals lacking this enzyme do not have methemoglobinemia. However, this enzyme is important in the treatment of methemoglobinemia. In the presence of certain redox compounds such as methylene blue, NADPH-MHb reductase rapidly reduces MHb to ferroheme. The response to methylene blue is both therapeutic and diagnostic. A rapid decrease in MHb occurs within 1–2 h if the cause of methemoglobinemia is due to an acquired toxic agent or a deficiency of NADH-MHb reductase. Failure to improve following administration of methylene blue suggests one of the M hemoglobins. It should be pointed out that G6PD deficiency per se is not a cause of methemoglobinemia, but rather it may cause a poor response to methylene blue because it is the primary source of NADPH.

### Biography

**Bertil Glader** received his PhD at the University of Illinois (Physiology, 1967) and MD from Northwestern University (1968). He was a pediatric intern at Stanford University (1968–1969). Following internship he served in the US Army as a research hematologist in the Department of Medicine at the Walter Reed Army Institute of Research (1969–1972). Subsequently he completed residency and hematology/oncology fellowship at the Children's Hospital Medical Center in Boston (1972–1974). He next was on the Pediatric faculty at Harvard (1974–1977), holding joint appointments in Medicine (Hematology/Oncology) at the Children's Hospital Medical Center and the Sidney Farber Cancer Center. Since 1977 he has been at the Stanford University School of Medicine where he is a Professor of Pediatrics (Hematology/Oncology) and Pathology. He also is also an attending Hematologist at the Lucile Salter Packard Children's Hospital at Stanford. He is the medical director of the RBC Special Studies Laboratory of the Stanford Clinical Laboratories. He is a co-editor of the textbook Wintrobe's Clinical Hematology. His clinical and research interests relate to acquired and genetic hematologic problems, with special focus on inherited red blood cell disorders.

# 73

## Hemophilias and Other Disorders of Hemostasis

*Jordan A Shavit and David Ginsburg*

### 73.1 OVERVIEW OF HEMOSTASIS AND THROMBOSIS

Maintenance of the integrity of the vascular tree is critical to all higher organisms with closed circulatory systems. A complex, highly regulated system has evolved for this purpose, consisting of extensive interactions between the endothelial cell lining of the blood vessel, the blood platelet, and an intricate cascade of plasma proteins (1,2). This complex system can be conceptually divided into three major limbs, as illustrated in [Figure 73-1](#). Although depicted as discrete compartments, multiple connections link these pathways to each other and to other homeostatic processes, including inflammation and tissue remodeling.

The first response to vessel injury often involves the platelet limb of hemostasis ([Figure 73-1](#)). Exposure of specific ligands in the injured vessel wall leads to the adhesion of blood platelets at the site of injury, subsequent platelet activation recruiting additional platelets, and activation of the plasma coagulation cascade. The coagulation cascade can also be triggered directly by tissue injury, exposing tissue factor (TF) to the plasma milieu ([Figure 73-2](#)).

These processes result in a temporary plug to the injured vessel composed of a mixture of fibrin meshwork and activated platelets. A complex response then ensues, resulting in breakdown and removal of the blood clot and repair of the injured tissue. The final regulatory cascade limb of hemostasis, referred to as the fibrinolytic system, serves to dissolve the blood clot, limiting the spread of the thrombotic process and speeding its resolution. The fibrinolytic and coagulation cascades are both characterized by sequential interactions between a series of plasma proteases and their specific cofactors and inhibitors. A number of regulatory feedback loops within the system serve to dampen the coagulation cascade, most notably the protein C anticoagulant pathway ([Figure 73-3](#)).

A shift in the delicate balance between the complex interacting limbs of the clotting cascade can result in pathologic thrombosis or hemorrhage. Considerable

insight into the functions of the various components of this system has come from characterization of the associated human genetic diseases. In addition, subtle variation at several of the genetic loci discussed in this chapter can also contribute to susceptibility to atherosclerosis, arterial thrombosis and venous thromboembolism, the leading causes of death and morbidity in developed countries. This chapter briefly reviews the biology of the plasma coagulation cascade, platelets, and the fibrinolytic system, as background for a discussion of the inherited bleeding and thrombotic disorders resulting from genetic defects in the components of these systems.

### 73.2 THE COAGULATION CASCADE

The coagulation cascade was historically one of the first biologic systems associated with human disease to be studied in detail at the biochemical level (3). This was due in large part to the ready availability of the relevant proteins through blood. Investigations over many years identified an ordered cascade consisting of a plasma protease activating an inactive zymogen target to an active protease form, which subsequently acts on the next step in the cascade ([Figure 73-2](#)). The components of the coagulation cascade were historically assigned Roman numerals, generally in the reverse order of their activation in the cascade ([Table 73-1](#)). Factors V through XIII are commonly referred to by their Roman numeral, whereas factors I through IV have more common names (fibrinogen, prothrombin, tissue thromboplastin (a combination of TF and phospholipids), and calcium, respectively). The term “factor VI” was abandoned when it was shown to simply represent the activated form of factor V (factor Va).

Although the clotting cascade was traditionally divided into the “intrinsic” and “extrinsic” pathways, the biologic significance of this distinction has been questioned. The extrinsic pathway is now viewed as the major mechanism of coagulation activation under most circumstances. The intrinsic pathway ([Figure 73-2](#)) begins with

**FIGURE 73-1** Overview of hemostasis. The platelet, coagulation cascade, and fibrinolysis limbs of hemostasis are illustrated schematically. Xa, factor Xa; Va, factor Va; VWF, von Willebrand factor; tPA, tissue plasminogen activator. See text for description.

**FIGURE 73-2** The coagulation cascade. See text for description. VWF, von Willebrand factor; HMWKin, high-molecular-weight kininogen; PreKal, prekallikrein. Other clotting factors are indicated by their Roman numeral designations.

the activation of factor XII (FXII) to FXIIa on surfaces such as glass, a property exploited in several laboratory tests. FXIIa, in the presence of high-molecular-weight kininogen then activates FXI to FXIa. FXIa activates FIX, feeding into the common portion of the coagulation cascade. The activated partial thromboplastin time (aPTT), commonly used in the clinical laboratory, primarily measures the activity of the intrinsic pathway. The absence of bleeding symptoms in patients with deficiencies of FXII

**FIGURE 73-3** Protein C anticoagulant pathway. When thrombin is bound to thrombomodulin, its protease specificity is altered and no longer efficiently generates a fibrin clot from fibrinogen. Instead, thrombomodulin-bound thrombin now specifically cleaves protein C to generate activated protein C (APC). APC proteolytically inactivates factor Va and factor VIIIa, aided by its cofactor, protein S. Va, active form of factor V; VIIIa, active form of factor VIII. Factors Va and VIIIa are critical components of the prothrombinase and Xase complexes, respectively.

or high-molecular-weight kininogen, despite marked prolongation of the aPTT (see later), suggests that these factors are not important physiologic activators of the coagulation cascade. By contrast, deficiency of FXI, the next step in the intrinsic pathway, is clearly associated with significant bleeding. This paradox appears to be explained by the demonstration of FXI activation by thrombin and autoactivation by FXIa. These reactions are thought to form an amplification loop, leading to additional activation of FIX by FXIa (4,5).

The coagulation cascade is now thought to be activated primarily through the so-called extrinsic pathway (now often termed “initiation” (6)), binding of FVIIa to TF on a cell membrane surface, with subsequent activation of FIX to IXa or of FX directly. FIXa and FXa

**TABLE 73.1** Components of the Classic Coagulation Cascade

Factor Number	Synonym	Chromosomal Localization
I	Fibrinogen	4q28
II	Prothrombin	11p11-q12
III	Tissue thromboplastin (TF and phospholipids)	1p21.3 (TF)
IV	Calcium	—
V	Proaccelerin	1q23
VI	Activated form of factor V (FVa; FVI no longer used)	—
VII	Proconvertin	13q34
VIII	Antihemophilic factor	Xq28
IX	Christmas factor	Xq27.1-q27.2
X	Stuart–Prower factor	13q34
XI	Plasma thromboplastin antecedent	4q35
XII	Hageman factor	5q33-qter
XIII	Fibrin stabilizing factor	6p25-p24 (A subunit)
	Plasma transglutaminase	1q31-q32.1 (B subunit)

are serine proteases, each of which forms a distinct membrane-bound complex with a specific cofactor, FVIIIa in the case of FIXa and FVa in the case of FXa. Factors V and VIII are highly homologous, nonenzymatic proteins that serve as essential cofactors for their cognate proteases. The FVIIIa/IXa complex, sometimes referred to as the X-ase (or tenase) complex, specifically cleaves FX to generate its active form, FXa. In turn, FXa interacts with FVa to form an enzyme complex referred to as “prothrombinase,” which specifically activates prothrombin to thrombin. Initiation generates a small amount of activated thrombin, which then feedback activates the intrinsic pathway (now often termed “amplification” and “propagation” (6)) by activating factors XI, VIII and V, leading to a “thrombin burst.” This excess of thrombin, the final protease in the cascade, acts directly on fibrinogen to generate the fibrin polymer that forms the structural basis of the blood clot.

TF expression is induced on endothelial cells and monocytes by inflammatory mediators such as tumor necrosis factor and endotoxin. In addition, cells in the subendothelium and tissues surrounding blood vessels express large amounts of TF. Thus, vascular injury initiates the cascade by exposing the coagulation proteins, including FVIIa, to TF. Although a low level of FVII is constitutively present in the circulation, it is inactive until it encounters TF. In the prothrombin time (PT) assay, coagulation is initiated by the addition of a crude brain extract that contains large amounts of TF on a lipid membrane surface. This assay is most sensitive to abnormalities in the vitamin K-dependent enzymes including thrombin, FVII, FIX, and FX. These factors share a common post-translational processing event that modifies selected glutamic acid residues to  $\gamma$ -carboxyglutamic acid. Vitamin K is an essential cofactor for this reaction

and thus vitamin K deficiency, or antagonism of vitamin K by warfarin, leads to bleeding as a result of the deficient function of these proteins.

### 73.2.1 Protein C Anticoagulant Pathway and Other Inhibitors of Coagulation

Figure 73-3 illustrates a negative feedback regulatory loop in the coagulation cascade, based on the activation of the anticoagulant serine protease, protein C, by thrombin. Abnormalities in this pathway are associated with several common inherited thrombotic disorders (see later). Although thrombin is normally a procoagulant protein, when bound to the transmembrane protein thrombomodulin, thrombin is converted from a procoagulant to an anticoagulant by changing its protease target specificity. Thrombomodulin-bound thrombin cleaves protein C to form activated protein C (APC). Accelerated by its cofactor protein S, APC proteolytically inactivates FVa and FVIIIa, thereby damping down the clotting cascade. Thus, activated thrombin can feed back on itself to turn off the activation of additional thrombin. As one might predict, deficiencies of protein C, protein S, and thrombomodulin are all associated with inherited thrombotic disorders. A remarkably common mutation in FV (factor V Leiden) renders FVa resistant to inactivation by APC, also resulting in a mild prothrombotic disorder.

Several important inhibitors also contribute to the regulation of the coagulation cascade, including TF pathway inhibitor, protein C inhibitor, and two specific inhibitors of thrombin, antithrombin III (AT3) and heparin cofactor II. AT3 also inhibits FXa and several other clotting cascade proteases. The inhibitory activity of AT3 is dramatically stimulated by heparin, providing the primary mechanism for the latter's anticoagulant function. Inherited deficiency of AT3 is associated with thrombosis (see later).

### 73.2.2 Platelets

Defects affecting the platelet limb of hemostasis can also result in abnormal bleeding. Platelets provide the most immediate response to vascular injury by forming a cellular plug at the site. Deficiencies in platelet number (thrombocytopenia) or platelet function (qualitative platelet disorders) are associated with abnormal bleeding. The major ligand facilitating binding of the platelet to the vessel wall is the multimeric plasma protein, von Willebrand factor (VWF) (Figure 73-1). Defects in VWF result in a platelet-like bleeding disorder, von Willebrand disease (VWD) (see later).

### 73.2.3 The Fibrinolytic System

The final limb of the hemostasis tree depicted in Figure 73-1 is provided by the fibrinolytic system. This proteolytic cascade results in dissolution of the fibrin clot. The

final enzyme in this pathway is plasminogen, a serine protease zymogen that in its active form (plasmin) specifically degrades fibrin and may also contribute to tissue remodeling through proteolysis of other matrix components. Plasminogen is activated by plasminogen activators (PAs), which include urokinase-type and tissue-type PA (uPA and tPA, respectively). Plasmin, as well as both PAs, are inhibited by specific serine protease inhibitors,  $\alpha_2$ -antiplasmin and PA inhibitor-1, respectively. Deficiencies of these inhibitors are associated with abnormal bleeding, whereas deficiency of plasminogen has recently been uncovered as the explanation for a rare autosomal recessive disorder, ligneous conjunctivitis (see later).

### 73.2.4 Inherited Disorders of the Coagulation Cascade

Inherited bleeding disorders due to deficiencies of factors within the coagulation cascade (Table 73-1) generally result in similar phenotypes. Hemorrhage into deep tissues, particularly the joints (hemarthroses), as well as increased bleeding following surgery or trauma, is characteristic. The pattern of bleeding can often be distinguished clinically from that associated with defective platelet function, as outlined in Table 73-2. Bleeding associated with coagulation cascade disorders is generally delayed compared to that of platelet defects. The latter is more often from mucosal surfaces, particularly the nose, oral cavity, and gastrointestinal tract, in contrast to the deep tissue hemorrhage characteristic of abnormalities in the coagulation cascade. These clinical differences can be quite useful in establishing a differential diagnosis. The PT and aPTT are typically used as screening tests for coagulation cascade defects and are generally normal in inherited platelet disorders. The bleeding time, although often unreliable and of questionable value as a screening test (7,8), should generally be prolonged in platelet disorders and normal in coagulation cascade defects. If the initial PT and aPTT screening tests are abnormal

or there are other reasons for clinical suspicion, additional workup, including specific factor assays, may be indicated. For most clotting factors, activity is measured in units, where 1 unit represents the activity present in 1 mL of normal plasma. Values may also be expressed as a percentage of the activity present in an equal volume of normal plasma. Pooled plasma from a large number of normal donors is generally used as a reference standard. Specialized platelet aggregation studies can be performed in suspected cases of platelet dysfunction. There is currently no reliable screening laboratory test for defects in the fibrinolytic system.

### 73.2.5 Hemophilias

The term *hemophilia* is generally reserved for two specific inherited X-linked disorders, FVIII deficiency (hemophilia A or classic hemophilia) and FIX deficiency (hemophilia B or Christmas disease), although FXI deficiency is sometimes referred to as hemophilia C. Other clotting factor deficiencies, particularly von Willebrand disease (VWD), are sometimes included in this general disease category. The latter is also characterized by decreased FVIII levels, as a result of the close association between these two proteins.

**73.2.5.1 Hemophilia A.** Hemophilia A is the most common inherited severe bleeding disorder. Its X-linked pattern of inheritance was first recognized by Jewish scholars in the second century AD, who exempted a male infant from circumcision if his mother and mother's sisters had other sons who had died of bleeding following their circumcisions (3,9). The syndrome was rediscovered in the late eighteenth and early nineteenth centuries and is often referred to as "classical hemophilia" (9–11). A number of cases of hemophilia occurred among several branches of the royal families of Europe, and for many years it was unclear whether these represented hemophilia A or B (12). However, advanced technologies including next-generation sequencing led to the recent identification of a causative mutation in the *FIX* locus (13).

FVIII is a nonenzymatic cofactor that is assembled on membrane surfaces together with FIXa to form the "X-ase" complex (Figure 73-2) that subsequently activates the zymogen FX to the active protease FXa. The central nature of this step in the cascade and the critical role of FVIII were largely revealed by the severe clinical manifestations of FVIII deficiency.

**73.2.5.1.1 Clinical Features.** The clinical manifestations of hemophilia A vary considerably from a severe bleeding disorder presenting at birth to a very mild condition that may be totally asymptomatic or only diagnosed very late in life (11,14,15). The severity of the disease can be predicted quite accurately from the level of residual FVIII activity (Table 73-3). Patients with very low or no FVIII activity (less than 1%) are affected with severe hemophilia A, whereas those with FVIII levels of 1–5% have moderate and those with 5–25% mild

**TABLE 73.2 Clinical Findings in Inherited Bleeding Disorders**

Parameters	Platelet-Type Defects	Coagulation Cascade Defects
Timing of bleeding	Early after trauma or spontaneous	Delayed
Sites	Skin and mucous membranes, petechiae, ecchymoses	Deep tissue hematomas, including joint, muscle and retroperitoneum
Inherited disorders	von Willebrand disease, Glanzmann thrombasthenia, Bernard–Soulier syndrome, other inherited platelet defects	Hemophilia A and B, factor V deficiency, deficiency of factors XI, VII, II, or X; afibrinogenemia

disease. FVIII levels above 25% are generally associated with a normal phenotype (Table 73-3). FVIII activity is measured in a clotting assay that titrates the capacity of a test sample to complement the defect in FVIII-deficient plasma, with 100%, or 1 U/ml, representing the comparable activity of normal plasma. In addition to this functional assay for FVIII activity, FVIII protein antigen can be measured using specific antibodies, although this assay is not generally available on a routine clinical basis. It is important to point out that FVIII and VWF circulate together as a tight complex in plasma, with VWF constituting approximately 98% of the mass of the complex. Thus, antibodies raised against this complex, historically referred to as FVIII-related antigen (FVIII:Ag), actually detect the VWF protein rather than FVIII and should be more correctly referred to as VWF:Ag. Unfortunately, many laboratories still use the old nomenclature, leading to considerable confusion. This test, (VWF:Ag or FVIII:Ag) is a standard part of the VWD workup. Although generally decreased in VWD, plasma VWF:Ag should be normal in hemophilia A. As noted earlier, the bleeding time is also generally normal in hemophilia A. FVIII deficiency can prolong the PT and aPTT, although the aPTT is usually more severely affected.

Hemophilia A should be suspected in any male with a severe congenital bleeding disorder and also in older males with mild bleeding. The diagnosis can usually be readily established by screening with the PT and aPTT, followed by the specific FVIII assay, with the level expected to correlate directly with the clinical course (Table 73-3). Although FVIII deficiency due to an acquired autoantibody inhibitor is not uncommon, these diagnoses can readily be distinguished in the laboratory by routine mixing assays between the test and control plasmas. The FVIII level can also be low in VWD. It is particularly important to distinguish hemophilia A from variants of VWD, especially type 2N (see later).

TABLE 73.3 Clinical Classification of Hemophilia A and B		
Classification	FVIII or FIX Activity (%)	Clinical Manifestations
Severe	<1	Spontaneous hemorrhage beginning in early infancy. Frequent hemarthroses; hemarthroses and other serious hemorrhages requiring factor replacement
Moderate	1–5	Hemorrhaging following trauma; occasional spontaneous hemorrhage
Mild	5–25	Bleeding generally only following significant trauma or surgery
	>25	No significant bleeding

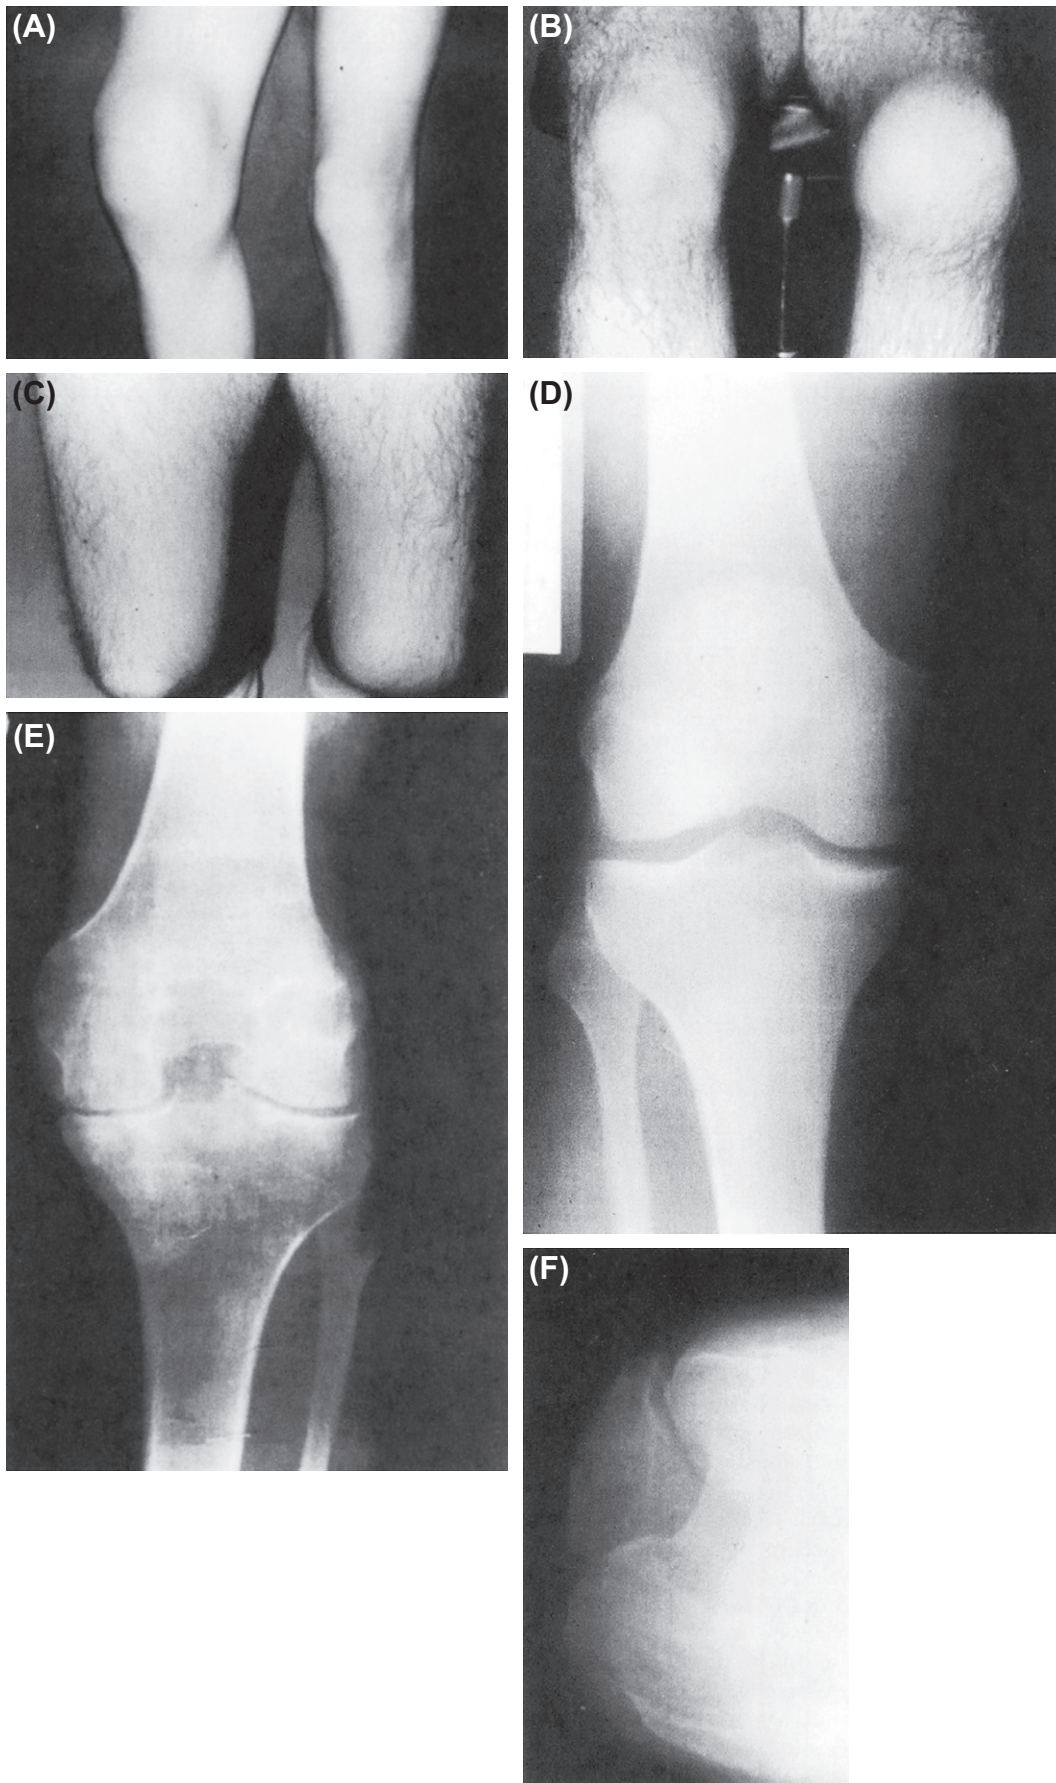

The typical clinical presentation in hemophilia A patients includes joint and muscle hemorrhages, easy bruising, and excessive, sometimes fatal hemorrhage after trauma or surgery. Hemarthroses are most common in the large joints, including the knees, elbows, ankles, shoulders, and hips. Although joint hemorrhage is generally triggered by stress or trauma, the precipitating event may not be recognized. Hemorrhage into joints is unusual until the child begins to walk, and the disease may go undiagnosed until that time. However, many severe hemophiliacs are diagnosed around the time of birth due to hemorrhage from the umbilicus or following circumcision.

Hemarthroses generally begin with mild pain and some limitation of motion. After several hours, pain will increase and joint swelling and warmth will be noted. Damage to the joint results from a chronic inflammatory reaction, and the resulting synovitis renders the joint more susceptible to repeat hemorrhage, leading to accumulated damage (Figures 73-4 and 73-5). Repeated bleeding into chronically inflamed joints results in the development of “target joints,” which are particularly susceptible to recurrent hemorrhage. The radiographic findings associated with the hemophilia joint are characteristic, although not significantly different between hemophilia A and B. Hemophilic arthropathy, with loss of cartilage and limited motion, often leads to permanent disability and may require joint replacement in selected cases. Such surgery can be accomplished safely under the cover of FVIII replacement (see later).

Other forms of internal bleeding may be more immediately life threatening. Large, intramuscular hematomas can result in compression, sometimes leading to specific compartment syndromes. Bleeding into other sensitive structures can lead to airway obstruction or other complications. Perhaps the most urgent type of bleeding is intracranial, accounting for about 25% of deaths among hemophiliacs prior to acquired immunodeficiency syndrome (AIDS). Another unique clinical problem seen in the hemophilias is the development of pseudotumors, cystic lesions arising from hematomas filled with a brownish necrotic core of debris surrounded by a thick fibrous wall. These lesions may also be complicated by infection. Hematuria frequently develops in patients with severe hemophilia during their lifetime. Although workup for structural defects is indicated, this is usually negative. A common complication is the development of ureteral obstruction by clots.

Modern treatment with FVIII replacement has resulted in a dramatic improvement in life expectancy from 11.4 years during the early 1900s to between 60 and 70 years in 1980. The AIDS epidemic has had a major impact on the hemophilia community and for a period during the 1980s to 1990s it was a central clinical manifestation of this disease. Most hemophiliacs receiving blood products prior to 1984 were exposed to the human immunodeficiency virus (HIV), with 60–70% of US and Western

**FIGURE 73-4** (A) Acute hemarthrosis. (B) Chronic hemophilic arthropathy particularly of the left knee demonstrating enlargement of femoral condyles with associated quadriceps wasting (C). Radiographs of right (D) and left (E) knees of the same individual illustrating rarefaction, enlargement of condyles and intercondylar notch and loss of cartilage along with degeneration of the patellofemoral surface (F).

**FIGURE 73-5** (A) Hematoma in calf. If inadequately treated, ischemic necrosis and subsequent fibrosis will ensue to give equinus deformity (B).

European severe hemophiliacs treated at that time subsequently becoming HIV infected (10,11,14,15). Many of these patients have developed overt AIDS, approximately two-thirds of whom have died. As a result, the median life expectancy for hemophiliacs between 1981 and 1990 dropped to 49 years (14). With improved screening and treatment of blood-derived factor, as well as recombinant factor products, this is no longer a major clinical issue.

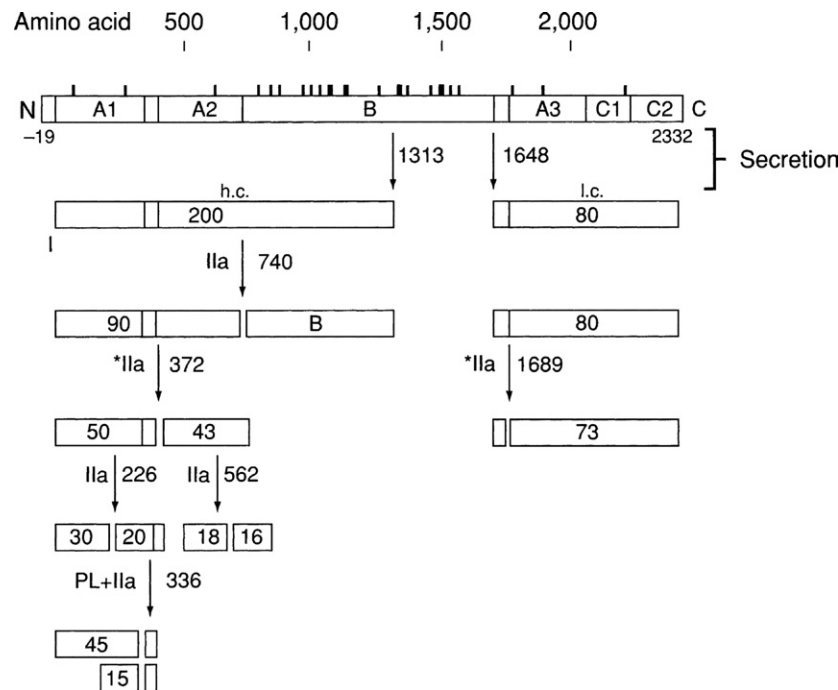

**73.2.5.1.2 Genetics.** The FVIII gene is located near the tip of the long arm of the X chromosome (Xq28). It is a large gene spanning 186 kilobases (kb), constituting 0.1% of the X chromosome, and is dispersed across 26 exons corresponding to a 9-kb mRNA (16). The FVIII protein sequence demonstrates a repeated structure, with three A domains, duplicated C domains, and a large central B domain, the last of which is encoded in a single exon (17–19) (Figure 73-6). The FVIII sequence and gene structure are highly homologous to FV (20). The B domain in both proteins appears to be a dispensable connector, since recombinant FVIII or FV from which the B domain has been deleted still maintains relatively normal function (21–23). The B domain is excised during FVIII activation, resulting in a heavy chain consisting of the A1 and A2 domains, and a light chain containing the A3, C1, and C2 domains, held together in a calcium-dependent fashion. Cleavage at arginine 1689 by thrombin liberates FVIII from VWF, allowing FVIII to bind to a phospholipid surface and interact with FIXa to form the X-ase complex (10).

A broad spectrum of genetic defects within the FVIII gene has been defined, resulting in a range of hemophilia phenotypes determined solely by the amount of residual

FVIII activity (10,24). The frequency of hemophilia A in most populations is estimated at approximately 1:5000 males (15). As predicted by Haldane, about one-third of cases appear to be new mutations, although this will likely decrease as the widespread availability of recombinant factor products leads to survival well beyond the reproductive years. Homozygous hemophilia A in females is predicted to occur at a frequency of less than 1:25,000,000 and such cases are indeed quite rare. Female hemophilia A may also result from hemizyosity for a FVIII mutation as a result of extreme inequality of lyonization or a translocation or other X-chromosome defect interfering with X inactivation. Finally, the type 2N VWD variant may also closely mimic hemophilia A, but with autosomal recessive inheritance (see later).

A large number of hemophiliacs have been studied at the DNA level (25) and a regularly updated database of known mutations can be accessed at <http://hadb.org.uk>.

Approximately 5% of patients carry deletions within the FVIII gene, generally leading to complete loss of protein expression. A variety of other defects, including frameshifts, nonsense mutations, and missense mutations, have also been described. In addition, several unique mechanisms for mutation have been identified in the FVIII gene. Two patients have been shown to have new LINE element insertions disrupting the FVIII gene (26,27). In addition, another novel mutation mechanism accounts for a large proportion of severe hemophilia A patients. Naylor and coworkers (28) initially observed an inability to amplify polymerase chain reaction (PCR) products crossing intron 22 from mRNA templates obtained from a large subset of severe hemophiliacs. Gitschier and coworkers (29) subsequently

**FIGURE 73-6** Domain structure and processing of factor VIII. The structural domains of factor VIII are depicted as A1, A2, B, A3, C1, C2. Vertical ticks indicate potential N-linked glycosylation sites. Thrombin cleavage within the B domain generates a 200-kDa heavy chain (h.c.) and an 80-kDa light chain (l.c.). Additional thrombin (IIa) cleavage sites are shown. PL indicates phospholipids and asterisks indicate thrombin cleavage sites required for activation of factor VIII. (From *Annu. Rev. Med.* 1992; 43, 325, with permission.)

demonstrated the occurrence of a large gene inversion in these patients, explaining the PCR results. This inversion occurs via a recombination between a small gene called gene A, located within intron 22 and one of two additional copies of gene A located upstream of the gene, toward the tip of the X chromosome. The resulting inversion (Figure 73-7) disrupts the FVIII gene and removes the C-terminus of the protein encoded by exons 23–26. Two mRNAs are transcribed from the inversion, one beginning in gene A and including exons 23–26, and the derivative of the original FVIII transcript, now containing only exons 1–22. This model explains the original observations reported by Naylor et al. (28) and leads to severe hemophilia A, with no detectable FVIII activity. Remarkably, this recurrent mutation is responsible for approximately 45% of severe hemophilia A (30). A very similar mutation mechanism was identified more recently, involving a repeated sequence in intron 1 of the factor VIII gene (31). This similarly results in a large gene inversion, which is also a recurrent source of mutation in hemophilia A, accounting for about 5% of severe cases.

About 20–30% of hemophilic patients develop clinically significant antibodies against FVIII (FVIII inhibitors), which severely complicate therapy. Inhibitor development is more frequent among patients with large gene deletions, or the factor VIII gene inversion, compared to those with other types of mutations. Patients with missense mutations that result in the synthesis of residual endogenous protein, even although nonfunctional, may develop immune tolerance, accounting for considerably lower inhibitor prevalence (as low

as 5%) (32). Currently, investigation into the etiology as well as novel therapy for inhibitors is a major focus of hemophilia research. This includes examination of associations with various unlinked polymorphisms, HLA genotype, and FVIII mutation (33,34).

**73.2.5.1.3 Clinical Management.** Treatment for hemophilia A rests on replacement of the deficient FVIII activity. Although long-term continuous FVIII replacement would most likely be curative for this disorder, this approach is currently not feasible, given the limited supply of material and its high cost. Hemophilia A was initially treated with unpurified plasma, which contains 1 U/ml of FVIII activity. The cryoprecipitate fraction of plasma was subsequently shown to be enriched for FVIII activity, thus permitting administration of a smaller volume. Over the past three decades, highly purified FVIII concentrates have become the mainstays of therapy for hemophilia A. Standard commercial concentrates are prepared from plasma that has been generally pooled from 2000 to 200,000 donors. Unfortunately, the purification processes used until the mid-1980s failed to inactivate common viral contaminants, including hepatitis B and C, cytomegalovirus (CMV), and HIV. As a result, all these infections were nearly uniform among patients heavily treated during the late 1970s and early 1980s. Following the identification of HIV, methods were developed to inactivate all these viruses by detergent or heat treatment. Monoclonal antibody purification procedures further improved the quality of these products. As a result, all currently available FVIII concentrates are thought to be free of most viral hazards, although there

The indicated crossover results in an inversion of the sequence between the two recombined A genes (C). (From Nat. Genet. 1993, 5, 236, with permission.)

remains concern about slow viruses or other unknown infectious agents (10,11,15). Recombinant FVIII production was a major goal driving the cloning of the *FVIII* gene in 1984 (18,35,36), finally reaching the clinic with approval of a commercial product in 1994. Although originally assumed to be free of viral contamination, the first-generation recombinant products may have occasionally transmitted several viruses of minor or no pathologic significance, including the B19 and TT viruses, raising the concern of the potential for transmission of the Creutzfeldt-Jakob disease agent, or other as yet unknown pathogenic viruses (15,37). The source of the virus appears to have been plasma-derived albumin used as a stabilizer, and this risk seems to be reduced or eliminated in the second-generation recombinant products, which are albumin-free (37).

Newly diagnosed and previously untreated patients are generally managed with recombinant FVIII or another highly purified plasma-derived product, with most clinicians preferring the former. There are also a number of newer recombinant products including B-domain-deleted FVIII, which is synthesized more efficiently and appears to have equivalent efficacy in vivo. A third-generation product manufactured and formulated in the absence of any human or animal protein is also available (15). Currently, manufacturers are working on the production of long-acting factor products to reduce dosing frequency through PEGylation of recombinant factor (33,38-40).

The type and level of treatment are dictated by the clinical situation. Many hemophiliacs are followed in comprehensive hemophilia treatment centers where they receive multidisciplinary care. A dose of FVIII of

approximately 50 U/kg will generally raise the FVIII level from 0 to 100%. The half-life of FVIII is approximately 8 h, requiring repeated doses every 8-12 h or treatment by continuous infusion for full replacement. Therapy is monitored by following the FVIII activity level. A FVIII level of 50% or greater should achieve normal hemostasis, even under extreme conditions. Full replacement doses are generally administered at the time of a major surgical procedure or trauma, with a gradual taper at an empirically determined rate following the procedure. Less severe trauma or surgical challenge is treated with less aggressive replacement. Patients often administer FVIII at home following minor trauma or at the first sign of hemarthrosis symptoms. Early clinical experience suggested that low-level, long-term prophylaxis could convert a severe hemophiliac to a moderate hemophiliac and dramatically improve long-term prognosis for both joint and other complications (10,11,41). This was borne out in a prospective, randomized clinical trial, although there was a nonsignificant trend to increased inhibitor incidence in the prophylaxis arm (42). Prophylaxis is now the standard approach for the treatment of newly diagnosed pediatric cases in most centers, with patients performing their own prophylactic infusions two to three times per week. Hemophiliacs can also be treated with desmopressin (DDAVP), which will result in a two- to fivefold increase in FVIII and VWF levels that can last a number of hours (43). This treatment is often sufficient to achieve adequate hemostasis in mild or moderate hemophiliacs. However, in severe hemophiliacs, DDAVP generally has minimal or no effect. Oral  $\epsilon$ -aminocaproic acid (EACA) and local methods are often adequate for

dental and other superficial procedures. However, major surgery or trauma often requires aggressive support with FVIII concentrates.

Approximately 20% of patients develop antibody inhibitors to FVIII that can dramatically complicate therapy. These antibodies can reach extremely high titers, and infusion of sufficient FVIII to overwhelm the inhibitor may often be impractical. A variety of strategies have been used to treat these inhibitors, including immunosuppression and various regimens to induce tolerance. Infusion of porcine FVIII is sometimes effective, as well as other specific factor concentrates that may “bypass” FVIII in the cascade and achieve improved hemostasis (10,11,15). Recently, recombinant FVIIa has been licensed for use in hemophilia patients with inhibitors. This product is rapidly becoming the treatment of choice in the setting of life-threatening hemorrhage in inhibitor patients, although its use is limited by high cost, which can exceed \$50,000 per episode (15,44).

While advanced recombinant products have virtually eliminated known infectious risks, the suggestion has been raised that these same products may result in an increased risk of inhibitor development (33). Certain FVIII products have been suggested to specifically increase risk. Alternatively, the absence of VWF in recombinant products has been proposed to increase FVIII exposure to the immune system. However, whether one or more recombinant factor products do indeed lead to increased inhibitor formation, and if so the underlying mechanism(s), remain controversial (40,45,46).

Gene therapy may offer an improved treatment for hemophilia A in the future. Tolerance of wide levels of FVIII without major negative sequelae and the need for only small increases in FVIII activity to achieve major clinical improvement make hemophilia A an excellent candidate for a gene therapy approach. At this time eight trials for either hemophilia A or B involving 50 patients have shown no significant toxicity using various vectors, including plasmid, retrovirus, adenovirus and adenovirus-associated virus (AAV) targeting liver, skeletal muscle and autologous fibroblasts. Complications have included modest and transient elevations in factor level and development of inhibitors, and thus there are major technical obstacles to be overcome (47–49). New methods have included various strategies tested in mouse models, such as expression of FVIII in hematopoietic stem cells, thus resulting in platelet delivery to sites of injury (49). A recent, and probably the first truly successful, human trial for hemophilia B using AAV is discussed below (50).

The modern molecular genetics of hemophilia A provide powerful tools for genetic counseling and prenatal diagnosis. Diagnosis of the common FVIII inversion is now routinely performed in a number of DNA diagnostic laboratories (30). This test will define the molecular defect in approximately 45% of severe cases and can serve as a diagnostic marker in other family members

at risk. Of particular importance for genetic counseling, it appears that the FVIII inversion generally only occurs during a male meiosis, possibly due to inhibition of inversion by the pairing of Xq homologs, which occurs during a female meiosis (30,51). Thus, if a new hemophiliac case has the inversion, the mother is generally a carrier, with the inversion having occurred in the germ line of the maternal grandfather. Somatic mosaicism is surprisingly frequent in hemophilia A, occurring in up to 13% of families, although more common in families with point mutations, particularly CpG transitions (52).

Efficient screening of all 26 FVIII exons and associated splice junctions can identify the molecular defect in the vast majority of hemophilia A cases not due to FVIII gene inversions. Such direct DNA sequence screening is available through several commercial DNA diagnostic laboratories. In rare patients for whom the precise mutation cannot be identified by direct DNA analysis, accurate genetic diagnosis usually can still be achieved by linkage analysis, which is routinely available through a number of DNA diagnostic labs. A number of intragenic polymorphisms are available that should lead to an informative analysis in over 90% of families. In questionable or uninformative cases, a fetal blood sample can be collected and plasma FVIII activity measured directly, providing definitive prenatal diagnosis. Although the ratio of FVIII to VWF is generally decreased in female hemophilia A carriers and was previously routinely used for carrier detection, the accuracy of this testing is limited and variable among individual laboratories.

**73.2.5.2 Hemophilia B.** The clinical features of hemophilia B closely resemble hemophilia A. Hemophilia B is also an X-linked recessive disorder with the defect due to deficiency of coagulation factor IX (FIX). As shown in Figure 73-2, FIX and FVIII interact to form the X-ase complex, which converts FX to FXa. Thus, it is perhaps not surprising that a deficiency in either of these factors results in a similar hemorrhagic phenotype. The FIX gene is also located on the long arm of the X chromosome, approximately 15 Mb from the FVIII gene. Hemophilia B, sometimes referred to as Christmas disease, is approximately one-fifth to one-tenth as common as hemophilia A, with an estimated prevalence of approximately 1:30,000 males (15).

**73.2.5.2.1 Clinical Features.** Hemophilia B was first distinguished from hemophilia A in 1952 by the demonstration of two distinct complementation groups through blood mixing experiments and given the name “Christmas Disease” after one of the first patients (3,9). As in hemophilia A, the clinical severity of hemophilia B can be closely correlated with the level of residual FIX activity with levels of less than 1% associated with severe disease and of 1–5% with moderate disease (Table 73-3). Hemorrhages are again typically in deep tissues, often involving joints and resulting in chronic hemarthroses. Intracranial hemorrhage is a major cause of death in hemophilia B.

**73.2.5.2.2 Genetics.** Hemophilia B also demonstrates typical X-linked recessive inheritance. Rare cases of females affected with this disease generally demonstrate extreme lyonization or an abnormality of an X chromosome. Although carriers usually demonstrate reduced plasma levels of FIX (in the range of 50%), these values are unreliable for carrier detection given the wide variation in FIX levels among normal females. More accurate classification of carriers and prenatal diagnosis in an “at-risk” pregnancy can usually be provided by linkage analysis or direct mutation detection. Where such testing is not possible, definitive prenatal diagnosis can also be established by fetal blood sampling.

The FIX gene is 34kb in length and contains 8 exons. The gene is located approximately 15 Mb toward the centromere from the FVIII gene. The gene encodes a 461-amino acid precursor protein. FIX is a member of the serine proteinase family and shows significant homology to other members. A signal peptide is followed by a propeptide domain that is post-translationally modified by the addition of  $\gamma$ -carboxyl groups to glutamic acid, a step dependent on vitamin K and required for function. FIX shares this feature with a group of vitamin K-dependent coagulation enzymes, including factors II (prothrombin), VII, and X, as well as protein C, protein S and protein Z (53). The regulation of FIX gene transcription has been extensively studied. A unique variant of hemophilia B has provided important insights into the regulation of FIX expression. This variant termed FIX Leyden, is associated with very low levels of FIX and severe hemophilia, but promptly improves at puberty with a rise of FIX levels to near the normal range (54) (Figure 73-8). A number of point mutations in the promoter region of the FIX gene, most within a 40-bp segment surrounding the major transcription start site, have been identified in these patients, contributing to the understanding of FIX gene regulation (54–56).

A large number of gross gene deletions, small insertions/deletions and point mutations have been identified in more than 2800 hemophilia B patients. A complete database of known mutations is maintained by a consortium of investigators in this field and can be accessed at <http://www.kcl.ac.uk/ip/petergreen/haemBdatabase.html>.

As for FVIII, inhibitor antibody formation is observed primarily in patients with large gene deletions, to a lesser extent with nonsense mutations, and rarely in patients with missense mutations (32). Point mutations occur throughout the coding sequence and also have been identified in positions interfering with splicing or other processing steps. The study of FIX gene mutations has provided valuable information about the general mechanism and rate of mutation in human populations. Approximately 1/3 of FIX gene mutations have been shown to occur at CpG dinucleotides (57) and approximately 1/3 of severe patients appear to represent new mutations, as also observed in hemophilia A and consistent with the original hypothesis of Haldane for X-linked lethal disorders. Analysis of a large cohort of hemophilia

**FIGURE 73-8** Factor IX Leyden. Factor IX activity levels in plasma as a function of age. Factor IX Leyden is associated with a severe hemophilia B phenotype that markedly improves after puberty. (From N. Engl. J. Med. 1982; 306, 788, with permission.)

B patients identified an overall human mutation rate of  $2.14 \times 10^{-8}$  per base per generation (or 128 mutations per human zygote), with an estimated 1% of these (approximately 1.3 per zygote) being detrimental (58).

Although no common recurrent mutation mechanism (as occurs in hemophilia A) has been identified in hemophilia B, the smaller size of the FIX gene makes direct DNA sequence analysis for mutation detection more straightforward. Such testing is available through several clinical DNA diagnostic laboratories. In addition, numerous polymorphisms have been identified within the FIX gene and can be used for linkage analysis for those cases in which a responsible mutation is not readily identified. DNA testing can thus be used for prenatal diagnosis or to definitively establish carrier status in at-risk females.

**73.2.5.2.3 Clinical Management.** Similar to hemophilia A, the treatment of hemophilia B is based on replacement with highly purified FIX concentrates or with recombinant FIX products. Management is generally similar to that of hemophilia A, and many of the experimental approaches discussed earlier for hemophilia A are being attempted for hemophilia B as well, including long-acting recombinant factor and inhibitor management. As with FVIII, the management of inhibitors to FIX is complex, although also improved by the availability of recombinant FVIIa (44). One particularly innovative approach is the oral ingestion of bioencapsulated FIX (expressed in plants) to induce tolerance in mice (46).

Although less common than hemophilia A, the much smaller size of the FIX gene has made hemophilia B an

attractive target for experimental gene therapy. A handful of human trials have been conducted to date, with only modest and transient increases observed in plasma FIX levels (48,49). Many of the experimental approaches discussed earlier for hemophilia A are being attempted for hemophilia B as well, including long-acting recombinant factor and inhibitor management, as well as gene therapy (see earlier). Two particularly exciting advances have been reported recently. The first was successful somatic cell genome editing using zinc finger nucleases. This achieved FIX expression levels of 1–5% in a mouse model of hemophilia B (59). Second was the first truly successful human gene therapy for hemophilia (50), with FIX levels maintained at 2–11% for 6–16 months with minimal to no side effects. Past clinical trials had demonstrated only transient correction possibly because of immune-mediated clearance of the viral gene therapy vector (49).

### 73.2.6 VWD

VWD is due to either a quantitative or a qualitative defect in VWF. In contrast to the hemophilias, where straightforward correlation between the level of factor activity and clinical phenotype can be made (Table 73-3), the clinical manifestations of VWD are bewilderingly complex, with extensive phenotypic and genotypic heterogeneity. Although VWD is considerably more frequent than hemophilia, the most common forms are generally quite mild and frequently go undiagnosed.

VWD was first described by Eric von Willebrand in 1926, who originally gave it the name “hereditary pseudohemophilia.” Considerable confusion existed for many years between this disorder and hemophilia A, since FVIII procoagulant activity is frequently also reduced in VWD. In addition, the antigen recognized by antibodies raised against the partially purified FVIII complex, composed primarily of VWF, was initially referred to as FVIII antigen. These antibody-based assays are now known to predominantly measure VWF. Thus, this factor, although normal in hemophiliacs, is generally decreased in VWD. VWD is also distinguished from hemophilia A by its generally autosomal dominant mode of inheritance.

**73.2.6.1 Clinical Features.** Multiple clinical subtypes of VWD have been described and an NHLBI expert panel recently formalized evidence-based guidelines for diagnosis and therapy (60). Traditionally, the most common variant of VWD, type 1, is associated with simple quantitative deficiency of VWF, with levels in the range of 3–50% of normal. Type 1 VWD appears to account for about 70% of clinically significant VWD (61,62), and inheritance is generally autosomal dominant with incomplete penetrance. The NIH Expert Panel (60) recommended that a definitive diagnosis of VWD generally be restricted to patients with VWF levels <30% of normal, given the significant overlap of levels of 30–50% with the lower range of the normal distribution. However, this does not preclude a diagnosis of VWD in patients

with 30–50% VWF levels, in the presence of additional supportive clinical or family history evidence.

VWF is a multimeric plasma glycoprotein that plays two major roles in hemostasis (63,64). First, it serves as an adhesive link between platelets and the blood vessel wall at sites of vascular injury (Figure 73-1). Second, it serves as the carrier for FVIII in plasma, with deficiency of VWF generally resulting in a corresponding decrease in the FVIII level. Mild VWD is generally associated with only modest decreases in FVIII, which should not contribute significantly to the bleeding tendency. The major cause of bleeding in mild VWD is related to the deficiency in platelet adhesive function. This bleeding resembles that associated with thrombocytopenia or a mild platelet functional defect. In contrast to the deep tissue bleeding of hemophilia, VWD patients suffer prolonged cutaneous or mucosal bleeding, such as spontaneous nosebleeds or gastrointestinal bleeding. More serious systemic bleeding is unusual but can complicate major surgery or trauma. Increased or prolonged menstrual bleeding is also a frequent complication in female patients who, as a result, are more likely to have the diagnosis established.

Bleeding time is a crude indicator of hemostatic function, determining the time to cessation of bleeding, following placement of a uniform superficial wound in the forearm. The bleeding time is typically prolonged in VWD and platelet disorders, but normal in hemophilia, although this test is notoriously unreliable and nonreproducible. False-positive and false-negative results are frequently observed. Aspirin can prolong the bleeding time in normal people as well as VWD patients. Although this has been suggested as a provocative test for VWD, the overall clinical utility of the bleeding time has been questioned (7,8). Automated platelet function testing devices are on the market to replace the bleeding time, but their clinical utility has not yet been clearly demonstrated (65).

The standard laboratory workup for VWD consists of bleeding time, and a series of coagulation tests, often referred to as the “VWD workup” (61). The latter includes FVIII activity, VWF antigen level (previously referred to as FVIII-related antigen or FVIII:Ag), and a ristocetin cofactor assay of VWF functional activity. All these three tests are generally proportionately decreased in typical type 1 VWD. In hemophilia, only FVIII activity is decreased. To properly subclassify the type of VWD, an additional test must be performed to examine the multimeric structure of plasma VWF. VWF multimer analysis is generally performed by agarose gel electrophoresis (Figure 73-9), although other techniques, including crossed immunoelectrophoresis, are sometimes used. In type 1 VWD, although VWF is quantitatively decreased, the multimer pattern is normal.

A number of less common variants of VWD have been distinguished, including types 2A, 2B, 2N, and 2M. Their features are summarized in Table 73-4. Type 2A VWD is associated with selective loss of large and intermediate-size VWF multimers, the forms of VWF that generally

**FIGURE 73-9** VWF multimer analysis. VWF multimers from plasma of patients with various qualitative variants of VWD are shown here, as analyzed by agarose gel electrophoresis. The brackets to the left encompass three individual multimer subunits including the main band and its associated satellite bands. The finer subclassification of VWD variants is often based on variations in these satellites. N, normal sample, 2A and 2B, type 2A and 2B VWD, respectively. (From Berkowitz, S. D.; Ruggeri, Z. M.; Zimmerman, T. S. *von Willebrand Disease. In Coagulation and Bleeding Disorders. The Role of Factor VIII and von Willebrand Factor*; Zimmerman, T. S., Ruggeri, Z. M. Eds.; Marcel Dekker, Inc.: New York, 1989, pp 215–259, with permission.)

exhibit the greatest adhesive function. Type 2B VWD is associated with spontaneous or increased binding of VWF to platelets, with subsequent clearance from circulation of the largest multimers, as well as platelets, resulting in thrombocytopenia and a multimer pattern similar to type 2A VWD. Type 2M VWD is often misdiagnosed as type 1 VWD, which has resulted in patient reclassification after analysis by VWF gene sequencing (66). In contrast to type 1 VWD, which has a VWF activity to antigen ratio close to 1, type 2M is characterized by a ratio less than 0.5–0.7, in the presence of normal VWF multimers (60).

Type 2N VWD, or VWD Normandy, is a unique variant associated with decreased VWF binding to FVIII (61,67). VWF function is otherwise normal. Homozygotes or compound heterozygotes for this condition can have moderately decreased FVIII levels closely resembling mild to moderate hemophilia A. However, this disorder is distinguished from hemophilia A by autosomal recessive inheritance and the decreased ability of plasma VWF to bind FVIII. The latter is also often reflected in a poor response to purified FVIII concentrates; thus differentiation of type 2N VWD from hemophilia A is of particular clinical importance.

A large number of other variants have been reported, many as isolated cases. These are generally distinguished by subtle abnormalities in the VWF multimer structure. A database of known VWD mutations and polymorphisms is maintained by a consortium of investigators in this field: <http://www.vwf.group.shef.ac.uk/>.

Type 3 VWD, the most severe form, is associated with extremely low or undetectable levels of VWF and generally also very low levels of FVIII (61). This disorder often appears to be autosomal recessive in inheritance, with parents unaffected or showing only borderline evidence for type 1 VWD. In other families, one or both parents may be affected with characteristic type 1 VWD. Type 3 VWD is associated with severe bleeding, both the mucosal type typical of type 1 VWD as well as the deep tissue bleeding characteristic of FVIII deficiency. Thus VWD testing should be included in the analysis of patients with severe FVIII deficiency, to avoid confusion between type 3 VWD and hemophilia A.

**73.2.6.2 Genetics.** The VWF gene is composed of 52 exons spanning approximately 180 kb on the short arm of chromosome 12 (68). There is also a nonprocessed partial pseudogene, localized to chromosome 22, that duplicates approximately the middle third of the VWF gene (exons 23–34). VWF encodes a 2813-amino acid protein composed of a number of internally repeated, homologous domains (Figure 73-10.)

A large number of genetic defects responsible for VWD have been reported. Gene deletion appears to be an uncommon mechanism, with only a limited number of cases identified. These deletions can include the entire VWF gene. Gene deletions, nonsense mutations, and frameshifts have been identified in a number of cases of type 3 VWD. A frameshift mutation in exon 18 is particularly common in Scandinavia and has been shown to be the defect in the original family described by von Willebrand (69,70). Several large-scale, multicenter sequencing efforts have provided new insight into the molecular genetics of type 1 VWD (71–73). VWF gene sequencing in approximately 330 type 1 families identified candidate mutations in 67% of index cases. Seventy-five percent were missense mutations scattered throughout the gene, and the rest were small insertions/deletions, splicing mutations, nonsense mutations, or promoter mutations (summarized in (74)).

Mutations have also been identified accounting for the majority of type 2A VWD, restricted primarily to the A2 repeat within exon 28 (Figure 73-10). These mutations have been shown to produce type 2A VWD via two distinct mechanisms (75). In group 1, a mutation results in the misfolding of the protein and retention in the ER, with multimerization accounting for the dominant negative effect. In group 2, multimers containing mutant subunits are secreted but show increased susceptibility to proteolysis in plasma, resulting in degradation of the largest multimers to smaller forms. The end result in both groups is similar, with loss of large multimers and a variable quantitative decrease in VWF. The plasma protease responsible for accelerated cleavage of type 2A VWF (76) is now known to be ADAMTS13 (a disintegrin-like and metalloproteinase with thrombospondin type 1 motif, 13). ADAMTS13 appears to be responsible for the physiologic processing of wild-type VWF

**TABLE 73.4 Summary of VWD Subtypes**

Subtype	Frequency	Clinical Features	Diagnosis	Molecular Basis
Type 1	1–10:1000; most common VWD variant (>70% of VWD)	Mild to moderate bleeding; autosomal dominant; incomplete penetrance (approximately 60%)	VWF:Ag, VWF:RCo, and FVIII all proportionately decreased (20–50 U/dl); normal multimer distribution	Some cases are heterozygotes for type 3 VWF
Type 3	1–5:10 <sup>6</sup>	Severe bleeding disorder; autosomal recessive inheritance	Markedly decreased or undetectable VWF:Ag, VWF:RCo, and FVIII	VWF gene deletions; nonsense mutations; frameshift mutations; other cis defects in mRNA expression; some cases are homozygous for type 1 defect
Type 2A	Approximately 10–15% of clinical VWD cases	Mild to moderate bleeding disorder; autosomal dominant, more complete penetrance than type 1; generally poor response to DDAVP	Variably decreased VWF:Ag, VWF:RCo, and FVIII; absent high and intermediate size VWF multimers with prominent satellite bands	Missense mutations clustered within VWF A2 domain; two subgroups: group 1, defect in intracellular transport; group 2, proteolysis in plasma after secretion
Type 2B	Uncommon variant (<5% of clinical VWD)	Mild to moderate bleeding disorder; autosomal dominant, more complete penetrance than type 1; ? DDAVP contraindicated	Variably decreased VWF:Ag, VWF:RCo, and FVIII; loss of large multimers; enhanced RIPA; thrombocytopenia	Missense mutations clustered in VWF A1 domain resulting in increased or spontaneous binding to platelet GPIb
Type 2M	Uncommon variants	Mild to moderate bleeding disorder; autosomal dominant; may respond to DDAVP	Variably decreased VWF:Ag, VWF:RCo, and FVIII; disproportionately low VWF:RCo relative to VWF:Ag; normal multimers	Missense mutations clustered in VWF A1 domain resulting in decreased platelet adhesion
Type 2N (FVIII binding defects; VWD Normandy)	Allele frequency may be as high as 1% in some populations	Variable bleeding disorder; homozygotes (or compound heterozygotes) may present as autosomal hemophilia A	Variable VWF:Ag and VWF:RCo; disproportionately low FVIII; generally normal multimers; decreased or absent VWF binding to FVIII	Missense mutations within the N-terminus of mature VWF, which interfere with FVIII binding
Platelet-type VWD (“pseudo-VWD”)	Rare (case reports)	Similar to type 2B VWD	Can be distinguished from type 2B by mixing studies with normal platelets and plasma	Missense mutation within GPIb $\alpha$ -chain resulting in increased or spontaneous binding to VWF

GP, glycoprotein; RIPA, ristocetin-induced platelet aggregation; VWD, von Willebrand disease; VWF, von Willebrand factor; VWF:Ag, VWF antigen; VWF:RCo, VWF ristocetin cofactor activity.

Modified from (253), with permission.

and deficiency of this protease is the cause of thrombotic thrombocytopenic purpura (TTP) (see later) (76–83).

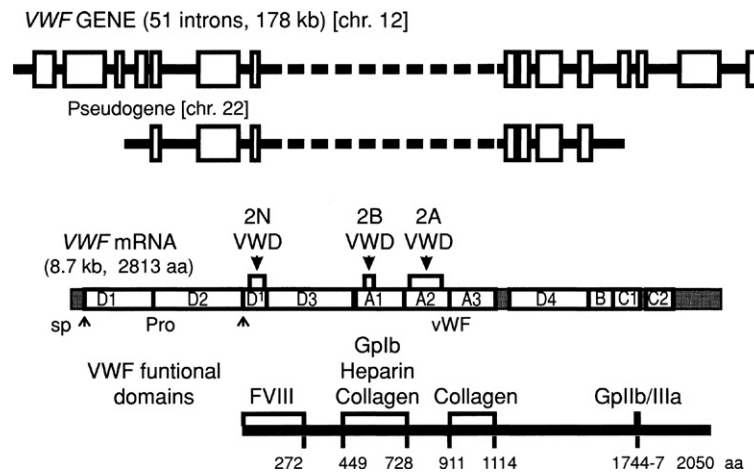

Type 2B VWD has been shown to be due to a limited number of mutations confined to the A1 repeat of VWF, corresponding to the binding domain for its major platelet receptor, GPIb (Figure 73-10). All these mutations appear to be “gain-of-function” mutations resulting in spontaneous or increased binding of VWF to platelets. Finally, a group of mutations has also been identified near the N-terminus of VWF, a region previously shown to contain the FVIII binding domain, which results in the type 2N variant of VWD, associated with decreased FVIII binding (61).

Type 2M is usually due to mutations in exon 28, which includes the A1 domain, the primarily functional

domain of VWF necessary for the ristocetin cofactor assay. These are usually missense mutations or in-frame deletions, and are autosomal dominant with a high degree of penetrance (84).

Although several examples have been reported (85), the frequency of new mutation in VWD appears to be low, consistent with the presumably modest decrease in reproductive fitness. It has also been proposed that mild VWD might actually provide some protection against pathologic thrombosis, including myocardial infarction (86). Consistent with this idea, high VWF levels are associated with venous and arterial thrombosis, at least in part through elevated FVIII levels (87–89).

Penetrance is decreased in type 1 VWD (approximately 60%) (90) and appears to be more complete in

**FIGURE 73-10** Structure of the VWF gene, mRNA, and protein. The VWF gene and pseudogene are depicted at the top with boxes representing exons and the solid black line, introns. The VWF mRNA encoding the full prepro-VWF subunit is depicted in the middle as the stippled bar and lettered boxes. The location of signal peptide (sp) and propeptide (pro-) cleavage sites are indicated by arrowheads below the bar, and the lettered boxes denote regions of internally repeated sequence. The clusters of mutations responsible for type 2A VWD, type 2B VWD, and FVIII binding defects (type 2N) are indicated above the bar. The approximate localizations for known VWF functional domains within the mature VWF sequence are indicated at the bottom. Numbers underneath the domains refer to amino acid residues within the mature VWF subunit. aa, amino acids, kb, kilobase pairs, chr., chromosome. (From Blood 1992; 79, 2507, with permission.)

type 2A and 2B VWD, although the latter has not been carefully studied. A number of factors contribute to the variable penetrance and expressivity of VWD. ABO blood group has been shown to modify VWF levels significantly and to account for about 30% of the genetic variance in plasma VWF antigen. VWF levels in type O individuals are on average 30–40% lower than those in type A, B, or AB (91,92). Families with higher heritability and lower VWF levels are more likely to have identifiable VWF gene mutations (93). Environmental effects also modify VWF levels, including estrogens, stress, underlying vascular disease, and thyroid dysfunction.

A novel locus modifying plasma VWF levels in the mouse results from altered lineage-specific expression of a glycosyltransferase, leading to aberrant glycosylation of VWF and accelerated clearance from plasma (94). Although this identical mutation is unlikely to occur in humans, similar polymorphic variation in post-translational glycosylation may account for significant alterations in plasma VWF levels and is likely the mechanism underlying the effect of ABO blood group on plasma VWF (95). Quantitative trait locus analysis using various mouse genetic backgrounds has identified additional polymorphisms, in the VWF gene and at other loci, contributing to the wide variation in plasma VWF levels among inbred mouse strains (96–98). There is some orthology between non-VWF loci in mice and humans, providing additional evidence that modifiers may be shared between the two species (96,98). Indeed, recent genome-wide association studies have confirmed ABO and VWF, as well as several other novel loci, in the control of human plasma VWF levels (99,100).

The true prevalence of VWD is controversial. Large screening studies have suggested that mild VWD may

affect about 1% of individuals in several populations (101,102). However, there is clearly overlap in VWF levels between normal and VWD patients and these prevalence figures and the criteria for a type 1 VWD diagnosis have been questioned (103). Prospective analyses of large primary care populations suggest that the prevalence of symptomatic disease is closer to 0.1% (104,105). A precise determination of prevalence must await more accurate and reproducible criteria for the laboratory diagnosis of mild VWD, possibly applying DNA diagnostic tools.

**73.2.6.3 Management.** The treatment of choice for mild type 1 VWD is the vasopressin analog DDAVP. Administration of DDAVP results in a two- to three-fold increase in VWF levels, lasting up to 6–12 hours (43,63). Although tachyphylaxis occurs after repeated use, administration every 12–24 hours is frequently sufficient to maintain adequate hemostasis. For most patients with baseline VWF levels in the 25–50% range, a two- to threefold increase is sufficient to bring VWF into the normal range. Adequate hemostasis can generally be obtained, even during major surgery. It is important to document an appropriate response to DDAVP by a test challenge prior to therapeutic use. The dose of DDAVP is generally 0.2–0.3 µg/kg, administered over approximately 20 mins by intravenous (IV) bolus. A high-concentration intranasal form of DDAVP has also been used successfully in patients, with considerably improved convenience and patient acceptance (43,63,106). As noted earlier, DDAVP is also an effective treatment in mild hemophilia A. DDAVP is generally ineffective in type 2A VWD, although some patients have been noted to respond, and is often considered contraindicated in type 2B VWD, where the release of abnormal VWF may lead to worsening thrombocytopenia and exacerbation of bleeding. Patients with type 2M

may or may not respond, but a therapeutic trial is warranted. DDAVP is of limited value in type 2N, although a therapeutic trial can be attempted. DDAVP is generally ineffective in type 3 VWD. Dental procedures in VWD patients can often be managed with oral EACA and local therapy.

In patients who are unresponsive to DDAVP or in whom DDAVP is contraindicated, the treatment of choice is factor replacement. Although recombinant VWF is used in the production of recombinant FVIII, it is removed during the purification process. A recombinant VWF product is currently in preclinical testing (107). Although effective, VWF replacement in the form of either fresh frozen plasma or cryoprecipitate is rarely used today, as standard treatment should generally be restricted to virally inactivated products. Several specific FVIII concentrate preparations containing large quantities of VWF of normal multimer structure, such as Humate-P, have been shown to be therapeutically effective (63). Most investigators view these preparations as the treatment of choice in patients unresponsive to DDAVP. It is important to emphasize that most standard plasma-derived FVIII concentrates do not generally contain useful VWF multimers, and many of the monoclonal antibody-purified preparations, as well as recombinant FVIII, are nearly devoid of VWF.

Prenatal diagnosis is not generally performed in the mild variants of VWD, given the minor bleeding usually associated with these conditions. For several of the subtypes, particularly type 2B VWD, a limited number of mutations account for the majority of patients and thus DNA analysis could be useful as a diagnostic test. Complete sequence analysis of the VWF gene, including the exons containing most type 2A, 2B, 2M and 2N mutations, has recently become available through several clinical laboratories. Testing of patient plasma VWF for reduced FVIII binding activity is also offered through specialized reference coagulation laboratories. As noted earlier, type 2N VWD is an important consideration in the differential diagnosis of mild to moderate hemophilia A, particularly if inheritance is not entirely consistent with an X-linked pattern. Prenatal diagnosis has been successfully performed by linkage analysis in a limited number of type 3 VWD families (108).

### 73.2.7 Pseudo-von Willebrand Disease

A unique platelet disorder has been described, termed pseudo-VWD or platelet-type VWD, which closely mimics type 2B VWD (109). This disorder is also associated with increased spontaneous interaction between plasma VWF and platelets and clearance of the complexes from plasma, resulting in thrombocytopenia and loss of large VWF multimers. However, mixing studies with normal platelets and plasma demonstrated that the defect in this disorder resides in the platelets rather than in VWF. The defect has been shown to be a gain-of-function

mutation in the GPIb receptor for VWF on the platelet surface (110,111), resulting in a phenotype similar to the gain of function within the VWF GPIb binding domain responsible for type 2B VWD. Replacement of VWF is ineffective in this disorder and treatment with DDAVP would appear to be contraindicated. Platelet transfusion is the treatment of choice, when treatment is necessary.

### 73.2.8 Factor XI Deficiency

After the classic hemophilias, factor XI deficiency is the most common inherited defect in the coagulation cascade (112). Factor XI deficiency is autosomal recessive and is particularly common among Ashkenazi Jews, with a heterozygote frequency of 9% in this population. One-half of all identified FXI deficiency cases occur in this population, with a much lower incidence in other groups. A number of point mutations in the FXI gene have been identified in affected patients, with two mutations accounting for greater than 90% of disease alleles among Ashkenazi Jews (113). Detailed haplotype analysis demonstrated an ancient founder allele for the common Glu117Stop mutation in this population (allele frequency 0.022), which apparently arose before the separation of Ashkenazi and non-Ashkenazi Jews. The Phe-283Leu mutation also common in this population (allele frequency equals 0.025) appears to have arisen more recently (114). A Cys38Arg founder mutation has also been identified in the French Basque population, with an allele frequency of 0.01 (115).

In contrast to hemophilia A or B, the plasma level of FXI does not always closely agree with the severity of bleeding. Occasionally, heterozygotes may also have significant bleeding. There does appear to be a correlation of phenotype with genotype, however, with the presence of hemorrhagic complications frequently breeding true in families. Significant bleeding complications are most often associated with FXI levels of less than 10%. Bleeding is most common after surgical procedures, including dental extractions. Hemarthroses are rare. Deficiency is often picked up by a screening aPTT, with specific FXI plasma activity assays available in specialized clinical laboratories. FXI deficiency has also been reported in several patients with Noonan's syndrome (116). Reported association of FXI deficiency with other clotting factor disorders, including hemophilia A and B and VWD, is probably due to the additive symptoms resulting from coincident occurrence of these relatively common defects. Dental and other minor bleeding can generally be managed with oral antifibrinolytic agents. When necessary, replacement with fresh frozen plasma can be used, preferably with a virally inactivated product. A FXI concentrate has been used in Europe, but may be associated with thrombosis. Patients who develop inhibitors can be treated with recombinant FVIIa (115).

### 73.2.9 Deficiency in Contact Activation Factors

Inherited deficiencies of FXII (Hageman factor), prekallikrein (Fletcher factor), and high-molecular-weight kininogen (Fitzgerald factor) have all been reported. These factors comprise the “contact” phase of coagulation, which also intersects with the fibrinolytic cascade and the kinin and complement systems. These disorders are primarily a laboratory curiosity, as they are generally not associated with clinically significant bleeding. Although a possible association between thrombosis and FXII deficiency has been proposed, this has not been confirmed in a large study (117). Diagnosis usually results from incidental identification of a markedly prolonged aPTT (more than 100 seconds) on a routine screening test. Inheritance of all three of these disorders is generally autosomal recessive, although possible autosomal dominant cases have also been reported. Differentiation among these three disorders requires specialized assays for the corresponding factors.

### 73.2.10 Disorders of Fibrinogen

The three fibrinogen genes,  $\alpha$ ,  $\beta$ , and  $\gamma$ , are located in a cluster on chromosome 4. Defects in any one of the three chains can result in markedly decreased fibrinogen (hypofibrinogenemia) or absent fibrinogen (afibrinogenemia) (118,119). Inheritance of afibrinogenemia is usually autosomal recessive, with consanguinity noted in many affected families. Over 150 families with congenital afibrinogenemia have been reported to date and a recent report suggests that over 80% of the mutations lie in the fibrinogen  $\alpha$ -gene, with the remainder most likely located within the closely linked  $\beta$ - or  $\gamma$ -genes. Although only a limited number of cases have been studied, the spectrum of mutations include a large gene deletion eliminating most of the fibrinogen  $\alpha$ -gene, as well as splice, frameshift, and nonsense mutations (118). Despite the central position of fibrinogen within the hemostatic system, symptoms can be surprisingly mild. Although the blood is unclottable *ex vivo*, bleeding generally appears to be less severe than in hemophilia A, a puzzling observation, given its downstream location in the cascade. Bleeding can be severe, however, and intracranial bleeding is the leading cause of death. Hemarthroses are also seen, as are mucosal and deep tissue bleeding. Pregnancies in afibrinogenemic females generally result in fetal loss. Reports of paradoxical thromboembolism have been noted in patients following replacement of fibrinogen. All the screening clotting tests, including PT, aPTT, and thrombin clotting time (TCT), are markedly prolonged, and the direct fibrinogen assays available in the clinical laboratory demonstrate absent fibrinogen. Bleeding time is also prolonged, probably due to a defect in platelet aggregation associated with the absence of fibrinogen. Hypofibrinogenemic patients rarely have significant

bleeding, unless the fibrinogen level is considerably less than 50 mg/dL. Therapy has generally been cryoprecipitate or fresh frozen plasma, although a fibrinogen concentrate is available (120).

Qualitative abnormalities in fibrinogen also occur and are termed “dysfibrinogenemia.” Defects in all three chains have been reported, resulting in abnormalities at all the possible stages of fibrinogen function, including cleavage by thrombin, polymerization, stabilization by FXIII, and fibrinolysis. Inheritance is generally autosomal dominant, indicating a dominant negative effect of the mutant subunit, since hypofibrinogenemic patients with 50% normal levels are generally asymptomatic. Clinical symptoms are varied, and about 40% of identified patients are asymptomatic, with 30% demonstrating hemorrhage and 10–15% thrombotic complications. A few patients have been seen with both hemorrhage and thrombosis. Both types of complications are generally mild, but fatal thrombosis or hemorrhage does occur. Recurrent spontaneous abortions and abnormal wound healing have also been described. The diagnosis is usually made on the basis of abnormal screening tests, with the TCT the most sensitive. Some dysfibrinogenemias result in shortening of the TCT, which may correlate with thrombosis. Fibrinogen concentration can be normal or low. Abnormalities in fibrinogen level must be distinguished from a wide variety of acquired disorders that alter fibrinogen level as well as acquired qualitative abnormalities. Many of these are associated with malignancy or autoimmune disease.

### 73.2.11 Factor XIII Deficiency

Factor XIII (FXIII) is a plasma and platelet-associated protein that cross-links the fibrin clot, significantly enhancing its stability. Clots not cross-linked by FXIII are much more easily lysed by the fibrinolytic system. Homozygous FXIII deficiency is rare with frequency estimated at less than 1:10<sup>6</sup>. Inheritance is autosomal recessive and can be due to defects either in the A subunit on chromosome 6 or in the B subunit on chromosome 1, with the vast majority in the former (119,121). Plasma levels in patients are generally less than 1%, and the disorder frequently presents with umbilical cord bleeding shortly after birth. Soft tissue hemorrhage and postsurgical traumatic bleeding are common and are classically described as being delayed by 1–2 days, although early bleeding can also be seen. Poor wound healing and abnormal scar formation are often noted. Intracranial hemorrhage is a particularly common complication and has been reported to occur in up to 25% of patients. All routine laboratory clotting tests are normal. The diagnosis is established by a urea clot solubility test since FXIII-deficient clots are readily lysed in 5 M urea, whereas normal clots are resistant. Treatment is with fresh frozen plasma or cryoprecipitate, which can be given as infrequently as every 4–6 weeks, since FXIII has an unusually

long plasma half-life (9–19 days). Concentrates of FXIII have been available in Europe, and are now available in the United States. Recombinant FXIII-A is now in phase III trials with promising results, although transient non-neutralizing inhibitors have been observed (121).

### 73.2.12 Defects in Other Coagulation Cascade Proteins

Prothrombin (factor II, FII) deficiency is quite rare, with only approximately 40 cases reported (119,122,123). Inheritance is generally autosomal recessive; defects in the prothrombin gene (chromosome 11), affecting most of the molecule, have been identified. Severity of bleeding is correlated with the level of prothrombin activity and varies from mild to severe. Residual activity has been seen in all patients and it has been speculated that complete deficiency of prothrombin is incompatible with life. Indeed, the generation of prothrombin-deficient mice by gene targeting (124,125) revealed a uniformly lethal phenotype in homozygous deficient animals. Compared to the much milder presentation of afibrinogenemia, these observations are consistent with the critical role of thrombin in platelet activation as well as fibrinogen cleavage, and potentially other processes. PT and aPTT are prolonged and TCT is normal. A specific factor assay is also available. Prothrombin complex concentrates are available and fresh frozen plasma can also be used for treatment.

Factor V (FV) deficiency is a rare autosomal recessive disorder, with an estimated frequency of 1:1,000,000 (119,122,126,127). The clinical presentation is very similar to that of hemophilia A and the disorder was originally referred to as “parahemophilia.” FV is found both in plasma and platelets and the relative contributions of these two pools to hemostasis are unclear. Some investigators have suggested a close correlation of bleeding symptoms with the platelet level of FV, and platelet transfusions have appeared to be effective therapy in some patients. However, standard therapy is fresh frozen plasma, as FV-containing concentrates are not currently available and FV is lost in the preparation of cryoprecipitate. Clinical symptoms are generally associated with levels of less than 1–20%, ranging again from severe to mild. PT and aPTT are prolonged and a specific FV assay is available. Bleeding time is also prolonged and may relate to the platelet FV pool. An unusual autosomal dominant variant of FV deficiency leading to moderate bleeding, known as FV Quebec, is associated with decreased platelet FV and a normal plasma pool (128). However, subsequent studies in these patients indicate that the reduced platelet FV is the result of a generalized accelerated proteolysis of  $\alpha$ -granule contents that is not restricted to FV alone (129), because of increased levels of urokinase-type plasminogen activator (PLAU) (130). These patients were recently shown to have a tandem duplication of the *PLAU* gene (131).

Residual low levels of plasma FV activity can be detected in nearly all FV-deficient patients, although a few examples of apparently complete deficiency have been reported, including a patient who is apparently homozygous for a frameshift mutation (132). Based on the observations that complete FV deficiency is uniformly lethal in mice, including death during midembryogenesis in a subset of animals, the occurrence of a similar early intrauterine loss in homozygous (or compound heterozygous) null human patients has been hypothesized to account for the milder defects observed in the majority of clinically ascertained patients (133). Consistent with this hypothesis, levels of plasma FV <0.1% of normal are sufficient to partially rescue the lethal hemorrhage in FV deficient mice (134), as are low levels of FV restricted to the platelet pool (135).

FVII deficiency has an incidence of 1:500,000 and has been associated with missense mutations in the FVII gene (chromosome 13) (119,122,136). Although hemorrhage is most likely with FVII of less than 10%, correlation with level is variable. Levels of less than 1% are associated with a bleeding pattern similar to that of classic hemophilia. The aPTT is generally normal and PT prolonged. A specific factor assay is available. Plasma or prothrombin complex concentrates are effective, although the treatment of choice is now recombinant FVIIa.

Factor X deficiency is a rare disorder with an incidence estimated at 1:1,000,000 (137). Analyses of patient DNAs have identified specific point mutations and deletions within the FX gene, located on chromosome 13 (119,122,137). Inheritance is autosomal recessive and the clinical presentation in severely deficient patients (activity less than 1%) is very similar to that of hemophilia. As in hemophilia, significant bleeding is rare, with levels above 10–15%. PT and aPTT are typically prolonged, and a specific factor assay is available. Treatment is with fresh frozen plasma or prothrombin complex concentrates. Recently, a FX concentrate that also contains some FIX has been developed (137).

A number of rare cases of multiple clotting factor defects have been reported. Inherited defects in the  $\gamma$ -carboxylase or vitamin K reductase pathways have been shown to account for combined defects in the synthesis of all the vitamin K-dependent factors, including FVII, FIX, FX, and prothrombin (138). Similar patterns are seen with vitamin K deficiency or with warfarin treatment. Several missense mutations in the  $\gamma$ -glutamylcarboxylase gene have now been identified in pedigrees with this disorder (138,139). This latter disorder is termed vitamin K clotting factor deficiency (VKCFD) with mutations in the  $\gamma$ -carboxylase enzyme termed VKCFD1. Recently, a second subtype of this disorder termed VKCFD2 has been shown to be due to mutations in the vitamin K2,3-epoxide reductase (VKOR) enzyme, which was first identified through a study of these patients (140). The same gene (VKORC1) was also independently identified through a direct expression cloning approach (141). This same

gene turns out to be responsible for warfarin resistance in mice and rats, where genetic mapping studies identified a syntenic region, contributing to the positional cloning. Polymorphic variations in VKORC1, as well as a cytochrome P450 gene, have also been identified as important determinants of warfarin sensitivity in human patients, accounting for 30–40% of the variance in warfarin dosing (142,143). Use of this pharmacogenetic information to guide therapy in patients has been suggested (144,145), although an improvement in patient outcome has not yet been demonstrated and such testing is not widespread in clinical practice (146).

An autosomal recessive disorder resulting in combined deficiency of factor V and factor VIII is particularly prevalent in non-Ashkenazi Jews (147) but has also been identified in a number of other populations. The gene responsible for this disorder was identified by positional cloning (148) and shown to encode the endoplasmic reticulum (ER)/Golgi intermediate compartment protein LMAN1 (also known as ERGIC-53). Complete deficiency for LMAN1 results in a coordinate decrease in both FV and VIII via partial block to the export of these specific proteins from the ER. Over 100 cases have now been identified with approximately 3/4 of studied patients found to be homozygous or compound heterozygous for null mutations in the *LMAN1* gene. The remaining subset of patients has a mutation in a second gene, *MCFD2* (149). *MCFD2* and *LMAN1* form a complex, which appears to function as a specific cargo receptor for FV and FVIII.

### 73.2.13 Platelet Disorders

#### 73.2.13.1 Inherited Disorders of Platelet Function.

A number of inherited disorders lead to congenital bleeding by interfering with the platelet limb of coagulation. All these disorders present similar clinical phenotypes, characterized by predominantly cutaneous mucosal bleeding and prolonged bleeding from minor injuries (Table 73-2). Petechiae and purpura are occasionally seen. Deeper tissue bleeding and hemarthroses are less common than in the coagulation cascade disorders, although serious central nervous system (CNS) hemorrhage can occur, particularly subarachnoid bleeding. By far the most common genetic cause of platelet-type bleeding is VWD, with the remaining inherited platelet disorders quite uncommon. A number of genetic platelet defects have been characterized in detail in the mouse (150,151), some of which may have relevance for human diseases.

**73.2.13.2 Bernard–Soulier Syndrome.** Bernard–Soulier syndrome is a rare disorder associated with platelet-type bleeding, unusually large platelets, and thrombocytopenia. The main functional defect in the platelet is loss of VWF-dependent platelet adhesion. Platelets in these patients have been shown to be missing the GPIb/IX/V complex on the platelet surface, the major receptor for VWF. Inheritance is generally autosomal recessive and frequently

associated with consanguinity. Most patients appear to have mutations within the GPIb $\alpha$  gene, although mutations in the GPIb $\beta$  and GPIX genes have also been identified (152,153).

**73.2.13.3 Glanzmann Thrombasthenia.** Glanzmann thrombasthenia is autosomal recessive in inheritance and, along with Bernard–Soulier syndrome, is the most clearly defined of the platelet functional defects at the molecular level (153,154). Platelets in this disorder show a profound defect in platelet aggregation. The clinical presentation is similar to that of other platelet functional defects. This disorder is due to absence or dysfunction of the GPIIb-IIIa ( $\alpha_{IIb}\beta_{III}$ ) integrin receptor on the platelet surface. This receptor plays a major role in platelet aggregation by binding to RGDS sites in fibrinogen and possibly other plasma proteins, including VWF. Inheritance is autosomal recessive; a variety of defects have been identified in both the *GPIIb* (*ITGA2B*) and *GPIIIa* (*ITGB3*) genes (153,154). Glanzmann thrombasthenia is sometimes divided into type I, characterized by complete absence of surface GPIIb/IIIa; type II, with GPIIb/IIIa antigen decreased to 10–20% of normal; and type III, with normal GPIIb/IIIa antigen but abnormal function. Type III appears to be due primarily to missense mutations in GPIIIa, whereas a variety of deletions and point mutations (many resulting in frameshifts or aberrant splicing) have been identified in type I patients, involving either the *GPIIb* or *GPIIIa* genes (155).

**73.2.13.4 Other Platelet Disorders.** A large number of rare congenital platelet disorders can be grouped together under the designation of storage pool deficiencies. A deficiency in any of several specific types of platelet storage granules can be seen, often requiring electron microscopic study for diagnosis. The gray platelet syndrome (GPS) results from the absence of normal  $\alpha$ -granules in megakaryocytes and platelets, although other granules appear normal. The inheritance is autosomal recessive, with only a few cases reported, occurring in both males and females. Recently, mutations in *NBEAL2* were identified as the cause of GPS (156–158). *NBEAL2* contains a domain that has been implicated in vesicular trafficking, suggesting a potential role in the development of platelet  $\alpha$ -granules.

Deficiency of dense bodies is also seen in some hereditary platelet disorders. Several of these conditions are associated with other clinical findings, including Hermansky–Pudlak syndrome, which is associated with ocular or oculocutaneous albinism. This disorder is particularly frequent in a restricted region of Puerto Rico. Abnormalities of this class of granules are also seen in other genetic syndromes, including Chediak–Higashi syndrome, thrombocytopenia and absent radii (TAR) syndrome, and Wiskott–Aldrich syndrome. In addition to the routine platelet studies described earlier, decreased serotonin uptake can often be documented in these conditions, serving as a marker for dense granule formation. Rare patients have also been described with defects in

platelet activation, affecting either the arachidonate or cyclooxygenase pathways. The precise molecular defects and the genetics of these latter disorders have not been clearly defined (153). A number of other rare disorders exist, both with and without additional constitutional phenotypes (159).

Treatment of all qualitative platelet disorders is primarily supportive, with platelet transfusion administered as necessary. Antiplatelet drugs such as aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided. Bleeding symptoms associated with selective serotonin reuptake inhibitors (SSRIs) may be secondary to depletion of this mediator from platelet granules, resulting in platelet dysfunction, and may act synergistically with NSAIDs (160). Estrogen and/or progesterone treatment is sometimes helpful for menstrual bleeding. Dental hygiene is important and antifibrinolytics are often useful to cover dental procedures. Iron deficiency anemia frequently develops from chronic low-grade mucosal blood loss. DDAVP may be of benefit in some patients, although the mechanism is not well understood. Given its relative lack of toxicity, a therapeutic trial with DDAVP is a reasonable consideration.

**73.2.13.5 Defects of the Fibrinolytic System.** Review of the complex coagulation regulatory system depicted in Figure 73-1 would suggest that abnormal overactivity of the fibrinolytic system could also result in pathologic bleeding (161). This is indeed the case. Although relatively rare, hereditary deficiencies of the fibrinolytic inhibitors  $\alpha_2$ -antiplasmin (162,163) and plasminogen activator inhibitor-1 (PAI-1) (164,165) have both been reported. These disorders would be predicted to result in overactivity of endogenous plasmin, resulting in accelerated clot lysis. Inheritance is autosomal recessive and is associated with the expected increased fibrinolytic activity and a mild to moderate bleeding defect, usually following minor trauma or surgery. Description of these defects provided the first strong indication that the major function of the plasminogen activation system is in the regulation of blood coagulation. Treatment is generally with one of the orally available antifibrinolytic agents that inhibit plasmin function such as EACA or tranexamic acid. The latter was available only in Europe and Canada until recently. Rare patients with abnormally elevated levels of tPA associated with a bleeding tendency have been reported (166), although some of these cases may represent deficiency of PAI-1 or another primary vascular defect (161).

Mild bleeding is also seen as a component of other genetic disorders. Abnormal bleeding into the skin is commonly observed in several types of Ehlers–Danlos syndrome. Hereditary hemorrhagic telangiectasia frequently is associated with nose bleeds and gastrointestinal (GI) blood loss. Earlier reports of an apparent association between VWD and hereditary hemorrhagic telangiectasia appear to have been ascertainment bias (167).

**73.2.13.6  $\alpha_1$ -Antitrypsin Pittsburgh.**  $\alpha_1$ -Antitrypsin Pittsburgh is an unusual disease observed in only two patients (168,169), but it is a highly instructive example of a dominant “gain of function” as a mechanism for human disease. This disorder is due to a single point mutation within the  $\alpha_1$ -antitrypsin gene resulting in substitution of an arginine for methionine at the P1 position (Met358).  $\alpha_1$ -Antitrypsin is a highly abundant plasma serine protease inhibitor (serpin) that inhibits the serine protease elastase. Deficiency of  $\alpha_1$ -antitrypsin results in a common genetic disease associated with emphysema and liver disease. The effect of the  $\alpha_1$ -antitrypsin Pittsburgh mutation is to convert  $\alpha_1$ -antitrypsin from an inhibitor of elastase to an efficient inhibitor of thrombin, an activity not exhibited in native  $\alpha_1$ -antitrypsin. The mutant  $\alpha_1$ -antitrypsin thus resembles AT3 in its activity. AT3 is the primary physiologic regulator of thrombin activity and deficiency of AT3 results in a hereditary prothrombotic condition (see later). Since  $\alpha_1$ -antitrypsin is present in considerably higher plasma concentrations, the  $\alpha_1$ -antitrypsin Pittsburgh mutation results in very high levels of AT3 activity. In addition,  $\alpha_1$ -antitrypsin is an acute-phase reactant and is markedly elevated during inflammatory challenges. The clinical presentation is a severe bleeding disorder that occurs at infectious illness, due to the resulting induction of  $\alpha_1$ -antitrypsin and the associated pathologic AT3 activity. The original patient died as a result of such a fatal hemorrhagic episode (168). The second patient enjoyed a considerably milder clinical course, possibly because of a counterbalancing inhibition of protein C (169). Although this mutation has not been transmitted, inheritance would be assumed to be a complete autosomal dominant, given the unique “gain-of-function” effect. Few human genetic diseases so clearly and elegantly demonstrate this important molecular mechanism.

### 73.3 INHERITED DISORDERS PREDISPOSING TO THROMBOSIS

Pathologic thrombosis is a major cause of morbidity and mortality in the United States. In addition, inherited abnormalities in coagulation balance may contribute to the development of atherosclerosis, leading to stroke and myocardial infarction. The multifactorial genetic determinants of atherosclerosis risk are just beginning to be elucidated.

Venous thrombosis, most commonly in the lower extremities, affects approximately 1 in 1000 individuals in the United States per year and is responsible for approximately 300,000 hospital admissions annually. The occurrence of venous thrombosis in patients under the age of 45, recurrent unexplained thromboses, or positive family history are all suggestive of an inherited predisposition to thrombosis or “thrombophilia.” Indeed, a positive family history can be elicited in

approximately 40% of young patients (170,171). Five well-defined genetic risk factors attributable to coagulation protein loss or gain of function have been associated with inherited thrombophilia: AT3 deficiency, protein C deficiency, protein S deficiency, the prothrombin G20210A mutation and factor V Leiden (172). The last variant is particularly common, and is found in 20–50% of patients with spontaneous venous thrombosis. However, no genetic susceptibility can be identified in 50% or more of patients and it is likely that a number of additional genetic risk factors for thrombosis remain to be discovered.

### 73.3.1 Antithrombin III Deficiency

AT3 is a member of the serpin gene family and a potent inhibitor of several serine proteases in the coagulation cascade including thrombin, factors IX, X, XI, and XII (1,2). The anticoagulant heparin acts by greatly potentiating the activity of AT3 against FIX, FX and thrombin. This function is presumably carried out by natural glycosaminoglycans *in vivo*. The hemostatic balance is very sensitive to variations in AT3. Levels in the range of 50% of normal are associated with a significantly increased risk of thrombosis, accounting for the autosomal dominant nature of this disorder. Although AT3 deficiency is generally defined as a level of less than 50% of normal, significant overlap can be observed between genetically deficient patients and normal individuals. The prevalence of AT3 deficiency is estimated at approximately 1 in 500–5000 (170,173,174).

**73.3.1.1 Clinical Features.** AT3 deficiency is generally subdivided into types I and II. Type I, or classic, AT3 deficiency is due to an absolute quantitative deficiency of the protein with corresponding decreases in antigen levels as well as functional activity by several assays. Type II deficiency can be associated with normal levels of antigen but decreased functional activity, generally due to point mutations within specific important functional domains such as the heparin-binding domain. Inheritance is autosomal dominant, although the penetrance of thrombosis is incomplete (see later). Although thrombosis can be spontaneous, it is often associated with other known risk factors such as pregnancy, contraceptive use, surgery, or trauma. The most common sites of thrombosis are in the deep veins of the leg and mesenteric veins; however, thrombosis at unusual sites can also occur. Recurrent thrombotic episodes are common, as are progression to pulmonary emboli. Arterial thromboses are rare, but have been reported in some severe cases. The typical age of onset of thrombosis is in the third to fourth decade of life. Although presentation in childhood and infancy has been reported, thrombosis before puberty is unusual.

Laboratory diagnosis is generally established by measuring AT3 antigen and functional activity. The

latter is usually measured as heparin cofactor activity, the most efficient initial screening test, which should detect defects of most types. A variety of acquired disorders can also result in decreased AT3 levels and should be distinguished from the inherited disorder. These include acute thromboses, chronic liver disease, nephrotic syndrome, and disseminated intravascular coagulation (DIC). Estrogens can also mildly reduce AT3 levels. Acute treatment with heparin also results in decreased AT3, presumably based on accelerated clearance. Thus, patients presenting with thrombosis should not undergo laboratory evaluation while on heparin. Because of these many confounding factors, an abnormal AT3 level should be confirmed with at least one additional measurement before establishing the diagnosis. Evaluation of other family members can also be helpful in supporting the diagnosis. The degree of thrombosis is often milder in patients with type II defects, presumably due to residual activity of the abnormal protein. Rare individuals with homozygous type II AT3 deficiency have been reported (170,173).

As noted earlier, the penetrance of thrombosis in heterozygous AT3 deficiency is incomplete. A review of published cases in the literature suggests penetrance of approximately 50%, although this figure may still represent an overestimate, due to greater ascertainment of more highly penetrant families. In contrast, careful analysis of a single large pedigree suggested that an unbiased penetrance figure is probably closer to 20% (175). This issue is of major importance in deciding whether to treat asymptomatic patients. Although the risk of thrombosis in asymptomatic AT3 carriers is probably greater than that in protein C, protein S and factor V Leiden (discussed later), the risk still is probably less than the major complication rate of long-term anticoagulation with warfarin (which may be as high as 1% per year). Most experts do not recommend routine long-term anticoagulation of asymptomatic carriers (170,173,176–178). One study suggests a risk for thrombosis of approximately 1.5% per year in AT3 carriers (176), 10–20 fold higher than the corresponding risk in normal individuals (177). However, overall, AT3 deficiency is associated with a normal survival and a low risk of fatal thromboembolic events (178). For this reason, anticoagulant prophylaxis is generally reserved only for individuals with additional significant risk factors or in particularly high-risk situations.

Although acute thromboses may be treated with thrombolytic therapy using guidelines similar to those for other cases of thrombosis, treatment is generally with standard or low-molecular-weight heparin (179). Difficulty in achieving adequate heparinization, or heparin resistance, may occur as a result of decreased AT3 and may initially suggest the diagnosis. AT3 concentrates have been used in selected clinical settings, particularly when standard anticoagulation is contraindicated. The

available products are of high purity and are not thought to carry viral risk. These purified concentrates are preferable to crude plasma products. The long half-life of AT3 (48 h) makes it feasible to raise levels above 80–100%. Standard long-term management of symptomatic AT3 deficiency generally relies on anticoagulation with warfarin. As noted earlier, asymptomatic patients are generally not treated with anticoagulants, given the significant long-term hemorrhagic risk, unless undergoing a procedure or treatment that significantly increases their risk of thrombosis. Pregnancy presents a particularly difficult management issue, given the teratogenic effects of warfarin (170,179). For the first time since the development of warfarin decades ago, several new oral anticoagulants have been approved, with varying availability in Europe and North America. These include small molecules that directly inhibit either thrombin or FXa at fixed doses without a need for routine laboratory monitoring (180), and that appear to exhibit fewer drug interactions than warfarin. However, these agents currently lack antidotes for emergent reversal of anticoagulation, and predominantly renal excretion complicates management in the setting of renal failure. The precise role of these new drugs, relative to warfarin, in adults as well as children remains to be fully defined.

**73.3.1.2 Genetics.** A single copy of the AT3 gene is located on human chromosome 1. A large number of molecular defects scattered throughout the gene have been catalogued ([www1.imperial.ac.uk/departments-of-medicine/divisions/experimentalmedicine/haematology/coag/antithrombin](http://www1.imperial.ac.uk/departments-of-medicine/divisions/experimentalmedicine/haematology/coag/antithrombin)), including a number of deletions, frameshift mutations, and nonsense mutations all resulting in type I AT3 deficiency, as well as missense mutations leading to type II. Structure/function studies of type II mutations have often demonstrated the molecular mechanism to be a specific defect in heparin binding or disruption of the active site, interfering with protease inhibition.

The diagnosis of AT3 deficiency is generally based on clinical AT3 antigen and functional assays, as described earlier. Although DNA diagnosis can be achieved on a research basis, this procedure is not routinely performed, given the large number of different mutations that have been identified. Although prenatal diagnosis by linkage or direct mutation detection is possible, it is generally not performed, given the usually mild nature of this disorder.

### 73.3.2 Protein C Deficiency

Griffin and coworkers (181) first identified protein C deficiency in 1981 in a family with recurrent thrombosis. Affected family members exhibited protein C antigen levels of less than 50% of normal. A large number of protein C-deficient patients have since been reported and their defects biochemically characterized.

Protein C is a protease zymogen that is activated when cleaved by thrombin bound to thrombomodulin on the endothelial cell surface. APC proteolytically inactivates factors Va and VIIIa on the platelet surface, thus downregulating thrombin generation by turning off the prothrombinase and X-ase complexes. In this way, thrombin autoregulates its own activity by activating the protein C anticoagulant pathway (Figure 73-3). The presence of thrombomodulin on the surface of vascular endothelial cells may serve to ensure vascular patency through this mechanism. Protein C deficiency removes this important balance, resulting in hypercoagulability.

**73.3.2.1 Clinical Features.** Protein C deficiency is an autosomal dominant disorder with prevalence estimated at approximately 1:500 (170,173,182,183). Estimates of the penetrance of protein C deficiency vary from as low as 20–30% to as high as 75%. In addition, the same mutation may vary widely in its expression in different families. Heterozygous deficiency results in protein C levels in the range of up to 50% of control, although there is considerable overlap with the lower portion of the normal range (183). Clinical presentation is similar to AT3 deficiency, with venous thrombosis usually presenting in the third or fourth decade, and rarely before puberty. A number of cases of homozygous protein C deficiency have been reported, associated with the severe form of neonatal purpura fulminans, which is fatal if not treated promptly (170,173).

**73.3.2.2 Genetics.** A large number of mutations in the protein C gene on chromosome 2 have been reported (184). Similar to AT3 deficiency, heterozygous protein C deficiency is divided into type I, or classic, associated with both low protein C antigen as well as functional activity, and type II, associated with normal antigen and decreased functional activity. The diagnosis of protein C deficiency is generally based on functional and antigen tests, rather than DNA diagnosis, given the large number of mutations that have been identified. Most type I patients have nonsense or frameshift mutations, or in some cases missense mutations.

Forty-three percent of the identified point mutations occur at CpG dinucleotides (184). The wide range in the degree of symptoms, even among families segregating the same mutation, has been puzzling. It is now clear that at least some of these cases can be explained by cosegregation of another prothrombotic mutation (see Factor V Leiden later). Protein C is a vitamin K-dependent protease that requires post-translational modification by  $\gamma$ -carboxylation at its N-terminus for full functional activity. Thus, warfarin treatment reduces functional activity, and to a lesser extent immunologic activity, making it difficult to diagnose this disorder during warfarin therapy.

**73.3.2.3 Management.** Anticoagulant management of protein C deficiency is similar to that described for AT3

deficiency (170,173). However, it is important to pre-treat for sufficient time with full heparinization before beginning warfarin anticoagulation, and to avoid large loading doses of warfarin. Abrupt initiation of treatment with a vitamin K antagonist has been associated with a dramatic thrombotic complication in the skin, referred to as “warfarin-induced skin necrosis.” This problem is thought to result from an imbalance between the anticoagulant effect of warfarin and the earlier, more rapid, inhibition of protein C. The latter effect results in an initial worsening of the relative protein C deficiency until sufficient inhibition of the coagulation factors II, VII, IX, and X has occurred to produce a net anticoagulant effect. If this complication should develop, treatment with fresh frozen plasma or protein C concentrate is indicated. Although purified protein C concentrates are not always routinely available, they have been used effectively in the treatment of children with homozygous protein C deficiency.

### 73.3.3 Protein S Deficiency

Protein S is a cofactor for the anticoagulant activity of APC (Figure 73-3). Thrombophilia due to heterozygous deficiency appears to be similar in frequency to protein C deficiency, and severe thrombosis has been reported in a few patients with apparent homozygous deficiency (170). It now appears that many cases previously ascribed to protein S deficiency may actually have been due to the APC resistance defect resulting from factor V Leiden. Some cases of protein S deficiency also appear to be associated with arterial thrombosis, a complication not generally seen in AT3 or protein C deficiency. However, this association is still controversial. Approximately 60% of protein S antigen in plasma is in a complex with the complement component, C4B-binding protein. Only the free fraction is functionally active as a cofactor. This interaction complicates the interpretation of protein S levels, as most screening tests measure only total protein S antigen. Type I deficiency is associated with a decrease in both total and free protein S antigen. Type II deficiency is characterized by normal free protein S antigen, but low protein S activity (APC cofactor activity). Type III is associated with a selective decrease in free protein S. The protein S gene and a homologous pseudogene are both located on human chromosome 3. Although a number of specific mutations leading to protein S deficiency have been identified, DNA testing is still limited to the research setting.

A study of a large cohort of well-established protein S-deficient patients and first degree relatives demonstrated that low free protein S level is the most reliable screening test for protein S deficiency. Patients carrying a protein S deficiency mutation showed a fivefold increased risk of thrombosis (185).

Clinical features of heterozygous protein S deficiency are similar to those of AT3 and protein C deficiency, with

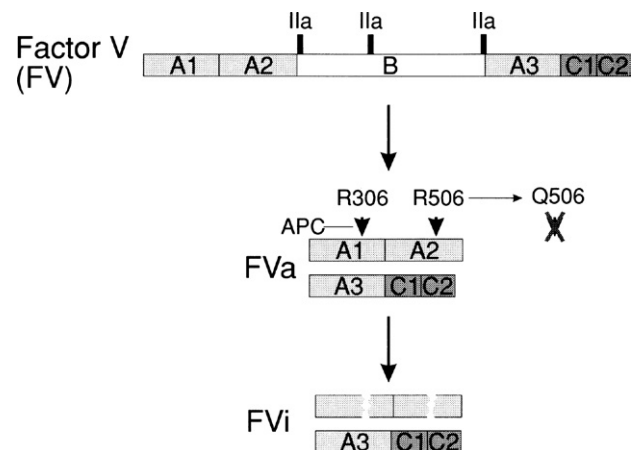

onset typically in the third or fourth decade. Acquired abnormalities in protein S can be associated with oral contraceptives, pregnancy, DIC, and acute thrombosis. In addition, C4B-binding protein is an acute phase reactant whose elevation in inflammatory states can be associated with a decline in free protein S activity. It is also important to note that protein S measurements can be difficult to interpret in patients on warfarin, since protein S also requires  $\gamma$ -carboxylation. Long-term treatment is similar to that described earlier for AT3 and protein C deficiency.

### 73.3.4 Factor V Leiden

Until the mid-1990s, deficiencies of AT3, protein C, and protein S were the only known thrombophilic risk factors. However, measurement of these factors generally detected an abnormality in only 5–10% of patients admitted with unexplained thrombosis (186).

Dahlbäck and colleagues (187,188) first reported a poor anticoagulant response to APC in three families with familial thrombophilia. These workers developed an assay based on prolongation of the PTT by the addition of APC. Affected individuals and their families showed resistance to this effect of APC. Inheritance of this APC resistance appeared to be autosomal dominant.

The responsible mutation was subsequently identified as a G  $\rightarrow$  A substitution at nucleotide position 1691 of factor V (189), resulting in the substitution of glutamine for arginine 506 (R506Q), a predicted protein C cleavage site within factor V (Figure 73-11). The R506Q mutation, commonly denoted as factor V Leiden, is found in 85–100% of individuals with APC resistance, depending

**FIGURE 73-11** Domain structure and processing of factor V. Thrombin cleavage sites (IIa) are indicated. FVa, the active form of factor V; FVi, factor V which has been inactivated through cleavage by activated protein C (APC). The APC cleavage sites at Arg306 (R306) and Arg506 (R506) are indicated. The common factor V Leiden mutation, substitution of glutamine for Arg506 (Q506), results in APC resistance.

on the specific assay used. APC resistance in the absence of factor V Leiden also appears to confer an increased risk for thrombosis, due in some cases to a lupus anticoagulant or other acquired disorder, although the cause often remains unidentified. Mutations at a second APC cleavage site within factor V (Arg306) have also been reported, including factor V Hong Kong (R306G) (190) and factor V Cambridge (R306T) (191). The R306G mutation appears to have a prevalence of ~4% in parts of Asia (190). Analysis of recombinant factor VIII indicates that mutations at the homologous APC cleavage sites in factor VIII do not produce APC resistance in the standard clinical assay (192) and no such patients have been reported.

Factor V Leiden has been identified in diverse populations, although it is particularly prevalent in Europe. Allele frequency among Europeans ranges from 2 to 7%, with the highest frequency observed in Greece. Haplotype analysis suggests a single founder for this mutation, who was estimated to have lived 21,000 to 34,000 years ago (193). This mutation appears to be quite uncommon in African and Asian populations (194).

Individuals homozygous for factor V Leiden have a high risk of thrombosis, with lifetime penetrance estimated at ~80%, compared to 10% in heterozygotes (170,173,195). Thromboses may appear at slightly younger ages in homozygotes (195), although this has not been confirmed in recent large cohort studies, where the major increase in thrombosis for both genotypes was not seen until after age 60 (196,197).

Oral contraceptives and hormone replacement therapy both confer an increased risk of thrombosis in factor V Leiden patients (170,198), although there is currently insufficient data to support routine genetic screening prior to initiating treatment (199). Together with the prothrombin G2021A mutation (see later), factor V Leiden is a major risk factor for thromboembolic complications during pregnancy and was observed among 44% of such patients in one study (200). The presence of both mutations resulted in a marked increase in the risk of thrombosis. Overall, the risk of thrombosis during pregnancy among factor V Leiden carriers was estimated at 0.2%, 0.5% for prothrombin G2021A, and 4.6% among patients with both mutations. However, no clinical benefit has yet been demonstrated for routine mutation screening (201), and current clinical guidelines only recommend prophylactic anticoagulation if there is a family or prior history of venous thromboembolism or homozygosity for one of these mutations (202,203).

The thrombosis associated with factor V Leiden appears to be restricted to the venous circulation with only limited controversial evidence for arterial thrombosis or increased risk of myocardial infarction. The prospective physicians health study of nearly 15,000 men confirmed an approximately 3.5-fold risk of venous

thrombosis in factor V Leiden carriers with no evidence of increased risk of myocardial infarction or stroke (204).

Given the remarkably high prevalence of factor V Leiden, its relatively low penetrance for thrombosis, and the lack of a significant effect on life expectancy (205) coupled with the significant morbidity of long-term anticoagulation with currently available drugs, no specific treatment can be recommended at this time for the asymptomatic patient, even those homozygous for the mutation. Patients who develop symptomatic thrombosis are currently treated using the same guidelines applied to the general patient population (206–208). Indeed, current evidence suggests that the risk of recurrent deep venous thrombosis is similar among carriers of factor V Leiden and patients without this mutation, as well as in patients with the prothrombin G2021A, or even in patients with both FV Leiden and prothrombin G2021A (209). Some experts recommend more aggressive anticoagulation in patients carrying more than one prothrombotic mutation or in patients also exposed to another risk factor such as pregnancy (210,211). However, this approach is controversial (208). It is likely that the approach to treatment will be refined over the coming years with the identification of additional high-risk groups and further definition of interactions between genetic and environmental risk factors.

APC resistance can be diagnosed by an APC resistance coagulation assay, which is available in many specialty coagulation laboratories. In addition, direct DNA mutation testing for factor V Leiden is clinically available. Given the lack of any specific changes in therapy, routine screening is not currently recommended (212). However, it is likely that such testing may eventually be shown to be of benefit in selected subgroups of patients. The remarkably high prevalence of factor V Leiden in European populations and its origin from a single founder mutation argue strongly against a significantly adverse effect on life expectancy and also suggest the existence of a positive evolutionary selective advantage for factor V Leiden carriers. A significant survival advantage for factor V Leiden patients in the setting of severe sepsis has been reported (213), suggesting that an infectious pathogen may provide balancing selection accounting for the exceptionally high prevalence of this polymorphism in some human populations. A reduced risk of intrapartum bleeding complications in factor V Leiden patients might also confer a survival advantage (214). In addition, factor V Leiden patients appear to have lower rates of pulmonary embolism, suggesting they may have an advantage of more stable thrombi (215,216).

### 73.3.5 The Prothrombin G20210A Mutation

Analysis of the prothrombin gene as a candidate for venous thrombosis predisposition identified a common mutation in the 3' untranslated region (G20210A) with

an allele frequency of approximately 1% in European populations. This mutation appears to be associated with elevated prothrombin levels, although elevated prothrombin level itself has not been found to be a risk factor for venous thrombosis (217). The G20210A mutation is at the 3' terminus of the 3' untranslated region and has been reported to increase the efficiency of prothrombin mRNA 3' end processing (218), although subsequent studies suggest other mechanisms for mRNA accumulation, including linkage disequilibrium to another nearby single nucleotide polymorphism (SNP) altering splicing efficiency (219).

The G20210A mutation leads to an approximately one- to sixfold increased risk of thrombosis. As in factor V Leiden, the thrombotic risk seems to be primarily restricted to venous thrombosis. However, an elevated risk for myocardial infarction in young women has been reported (220). The overall thrombosis risk conferred by prothrombin G20210A appears to be somewhat lower than that of factor V Leiden, which in turn appears to be somewhat less than that of AT3 deficiency (207).

### 73.3.6 Other Miscellaneous Prothrombotic Disorders

A number of other conditions have been associated with thrombosis but are not generally considered in a routine evaluation. These include rare qualitative abnormalities in fibrin function referred to as dysfibrinogenemias. This heterogeneous group of disorders can present either with a bleeding diathesis or with recurrent thrombosis (see earlier). Deficiency of FXII (Hageman factor) was thought to be associated with thrombosis, but this has not been confirmed (117). With the recent discoveries of highly prevalent mutations in factor V and the prothrombin gene leading to predisposition to thrombosis, increased analysis of other clotting factor genes has identified new potential prothrombotic risk factors, although none are well defined at this time. A high level of factor XI has been reported as a risk factor for thrombosis, with doubling of the risk at levels present in the upper 10% of the population. Although the genetic basis for this variation in factor XI remains unknown, if confirmed, this additional factor could be an important genetic contribution to thrombophilia (221). A similar association of elevated factor IX levels with thrombosis risk has also been reported (222). Recently, a novel FIX variant (FIX Padua, R338L) was discovered in a patient with thrombosis who had an eightfold increase in FIX activity (223). However, follow-up studies have not yet identified other individuals with this variant outside of the proband's family. In several studies, plasma factor VIII level has been found to be an important determinant of thrombosis risk. In one analysis, elevated factor VIII was calculated to account for 16% of the population-wide attributable risk for thrombosis, compared to 25% for factor V Leiden, 4% for prothrombin 20210A, 2%

for protein C deficiency, and <1% for protein S and AT3 deficiency (224). Patients with elevated plasma factor VIII may be at particularly high risk for recurrence (225). Family studies suggest that elevated factor VIII levels are at least in part genetically determined (226,227) and do not appear to be linked to the factor VIII locus itself. A recent report suggests a potential role for imprinted loci on chromosomes 5 and 11 (228), although the responsible genes remain to be identified. As noted earlier, abnormalities in fibrinogen, particularly the dysfibrinogenemias, can also be associated with thrombosis (170).

Premature atherosclerosis and venous and arterial thromboses are well-known complications of the autosomal recessive genetic disorder, homocystinuria due to cystathionine synthase deficiency. These patients appear to have a particularly increased risk of venous thrombosis when factor V Leiden has been coinherited (229). Even modest elevations in plasma homocysteine, which may result from heterozygous deficiency or other dietary or genetic influences, may be a significant independent risk factor for the development of atherosclerosis (230). Mild homocystinemia may also be an independent risk factor for venous thrombosis (231), although this hypothesis is controversial since homocysteine lowering therapy has not been effective for the prevention of recurrent thrombosis (232,233). A very common polymorphism in the MTHFR gene (C677T), leading to a thermolabile enzyme, exhibits an allele frequency as high as 38% in some populations, with homozygous frequencies as high as 12% (234). Homozygosity for the 677T MTHFR allele may be associated with elevated plasma homocysteine levels, particularly in the setting of folate deficiency. However, it does not appear to confer an increased risk for ischemic heart disease or venous thrombosis (235,236), even when coinherited with factor V Leiden (237,238).

### 73.3.7 Plasminogen Deficiency

Inherited defects of fibrinolysis are a rare cause of familial thrombosis. Although a number of cases of partial plasminogen deficiency have been reported, the association with thrombosis is controversial (161). Plasminogen deficiency has been classified as type I deficiency, with reduced antigen and functional activity and type II deficiency in which antigen is normal but functional activity is proportionately decreased. Type II deficiency due to an Ala600Thr mutation is very common in the Japanese population with an allele frequency of about 1%. This mutation was initially identified in a patient with thrombosis (239). However, other family members were unaffected. Although a number of other missense mutations within the plasminogen gene have been identified, partial deficiency of plasminogen does not appear to be a significant risk factor for thrombosis, with similar prevalence observed among thrombosis patients and controls (240,241).

Complete plasminogen deficiency in knockout mice (242,243) results in severe and widespread chronic thrombosis. Failure to observe a similar disorder in humans led to the presumption that such a condition would be lethal. However, homozygosity for null mutations in the plasminogen gene was subsequently shown to be the molecular basis for a rare ophthalmologic disorder, ligneous conjunctivitis (244) (reviewed in (161)). This disorder usually presents first in early infancy as a chronic, pseudomembranous conjunctivitis, although symptoms can be delayed into adulthood. The membranes that form over the eyes have a woody consistency and may follow minor trauma or infection (Figure 73-12). These membranes can occur on other mucosal surfaces in the oropharynx, trachea, or female genital tract. Congenital hydrocephalus is also noted in a subset of patients. Inheritance is autosomal recessive. In 1997, Schuster et al. (244) reported two patients with ligneous conjunctivitis who were each homozygous for a different mutation in the plasminogen gene, associated with undetectable plasminogen activity and antigen. Five additional patients were subsequently reported, with the range of mutations and phenotypes observed suggesting a correlation between residual plasminogen activity and severity of disease (245). Treatment of one of the original patients, who was homozygous for a nonsense mutation (Glu460Ter), with a plasminogen concentrate prepared from human plasma produced a dramatic clinical response (246). Remarkably, there have been no reports of thromboembolic complications

in ligneous conjunctivitis patients or their families, suggesting that the primary role of plasminogen in humans is in the clearance of extravascular fibrin. A careful reanalysis of plasminogen-deficient mice identified ocular lesions very similar to human ligneous conjunctivitis, but that were undetected in the initial evaluation of these animals (247).

No genetic deficiencies of tPA or uPA have been reported in humans. Several families have been described with reduced fibrinolytic potential that could be due to either over production of PAI-1 or deficiency in tPA (170). Although laboratory tests for plasminogen are available, routine screening in families with thrombosis is not generally indicated.

### 73.3.8 Thrombotic Thrombocytopenic Purpura (TTP)

TTP is a catastrophic, multisystem disorder characterized by the formation of platelet and VWF-rich microthrombi in vessels of multiple organs, leading to the classic pentad of microangiopathic hemolytic anemia, thrombocytopenia, fever, and varying degrees of renal and CNS dysfunction (80,248). Not all of these manifestations are present in all patients, although thrombocytopenia and hemolytic anemia are nearly universal. Typical age of onset is in the second or third decade, although this disorder can be seen at any age and there is usually no clear precipitating event. Untreated, mortality is greater than 90%, although with plasma exchange this figure falls

**FIGURE 73-12** Ligneous conjunctivitis. (A) The initial appearance of a child with ligneous conjunctivitis resulting from homozygous plasminogen deficiency. (B) The same child after 7 months of replacement with Lys-plasminogen. (Adapted from N. Engl. J. Med. 1998; 339, 1679, with permission.)

to 10–20 (248,249). Most adult cases are sporadic and associated with the presence of acquired autoantibodies against a plasma metalloprotease that cleaves VWF (78,83). Absence of this VWF-cleaving protease results in accumulation of unusually large multimeric forms of VWF, which are thought to trigger the pathologic platelet thrombi responsible for TTP (80,248). A rare familial form of TTP, also referred to as Upshaw–Schulman syndrome, typically presents at birth or in early childhood and is usually highly responsive to the infusion of normal plasma (248). The gene responsible for this rare autosomal recessive disorder was identified by positional cloning as the metalloprotease, ADAMTS13 (81). It was independently identified at the same time by others as the VWF-cleaving protease previously associated with this disorder (77,79,82). A range of mutations scattered throughout the ADAMTS13 gene have now been identified and appear to account for all cases of familial TTP, with no evidence to date for locus heterogeneity (80,81). Patients with the familial form of TTP can generally be managed with simple plasma infusion, which presumably replaces the missing enzyme. Plasma exchange in adult patients with acquired disease may serve to partially remove autoantibodies, in addition to protein replacement (248,249).

### 73.3.9 Interactions among Multiple Genetic Defects

The discovery of the very common factor V Leiden mutation has also shed light on the penetrance of other less common familial hypercoagulable states. The risk of thrombosis varies considerably among protein C-deficient families. In some families, inheritance appears to be recessive and in others, dominant. In some cases, the same mutation has been found in families of both types. Koeleman and coworkers (250) assessed the effect of factor V Leiden on the penetrance of protein C deficiency-related thrombosis. These workers observed a prevalence of the factor V Leiden mutation of 19% among symptomatic protein C-deficient patients, compared to a 2–4% incidence in the control population. In six large pedigrees, 73% of patients inheriting both gene defects experienced thrombosis, compared to 31% of patients with only the protein C defect and 13% of the patients with only factor V Leiden. Similar interaction of the factor V Leiden mutation with protein S deficiency has also been noted (251), as has an increased risk of thrombosis associated with coinheritance of factor V Leiden and the prothrombin G20210 gene mutation (see earlier).

Thus, venous thrombosis, like many other common, complex disorders, can be viewed as the product of interactions between a number of genetic and environmental factors. Factor V Leiden, the prothrombin 22010 mutation, and likely a number of other common, yet to be identified genetic factors combine with environmental factors such as pregnancy, immobility, and underlying

malignancy to determine the overall thrombosis risk for each individual. The strong foundation already in place for the basic biochemistry and physiology of blood coagulation should greatly facilitate deciphering the interactions between these multiple factors, eventually leading to accurate predictions of risk and individually tailored therapy. In this way, the treatment of thrombosis may serve as a valuable paradigm for other complex genetic disorders.

## 74.1 HISTORICAL BACKGROUND OF RH ALLOIMMUNIZATION

The first recorded case of hemolytic disease of the newborn was described in 1609 by Louyse Bourgeois, a French midwife. The first of a pair of twins was hydropic and died shortly after birth. The second was well at birth, but became deeply jaundiced and died a few days later. In 1932, Diamond et al. (1) showed that hydrops fetalis, icterus gravis, and kernicterus were different presentations of a single, as-yet unidentified, disease characterized by hemolytic anemia, extramedullary erythropoiesis, hepatosplenomegaly, and erythroblastosis, which they termed “erythroblastosis fetalis.”

Darrow (2), in 1938, suggested that fetal hemoglobin crossed the placenta and stimulated maternal production of a fetal hemoglobin antibody, which crossed back into the fetal circulation, causing destruction of the fetal red blood cells (RBCs). The involvement of the Rh antigen in erythroblastosis fetalis was discovered in 1939 by Levine and Stetson (3). The mother of a stillborn baby, who had been given a postpartum transfusion of blood donated by her husband, experienced a severe transfusion reaction. Antibody was detected in her serum, which agglutinated RBCs from 80% of randomly selected type O donors. The antibody specificity was identical to that of antibodies raised in rabbits injected with erythrocytes from rhesus monkeys, hence “antirhesus” or “anti-Rh” (4). The cause of fetal hemolysis was the production of maternal anti-RhD alloimmune antibodies was proved by Chown in 1954 (5,6). An RhD-negative primigravida, with no anti-D at the time of delivery, gave birth to an anemic infant with erythroblastosis and hepatosplenomegaly. The result of the direct antiglobulin test was negative for fetal erythrocytes, and at delivery, the mother appeared to be weakly RhD positive. Chown showed that many of her circulating erythrocytes were RhD positive and of fetal origin,

suggesting that a very large fetomaternal hemorrhage had occurred. Within 20 days after delivery, the woman produced a strong anti-D reaction and her subsequent pregnancies were severely affected by erythroblastosis fetalis.

## 74.2 ETIOLOGY OF ALLOIMMUNIZATION

In 1953, Chown demonstrated that the cause of Rh immunization was the passage of Rh-positive fetal erythrocytes into the maternal circulation. The risk of Rh alloimmunization is 16% if the Rh-positive fetus is ABO-compatible with its mother. If it is not Rh compatible, then the risk approximates 2%. The risk increases if invasive measures such as amniocentesis, chorionic villus sampling, or fetal blood sampling is undertaken to evaluate for a fetomaternal hemorrhage (7).

Approximately 50% of Rh-positive newborns with Rh hemolytic disease of the newborn are mildly affected. These newborns usually do not require treatment. However, 25% will be born near term in stable condition. Whereas 10% of these newborns may become extremely jaundiced and either succumb to kernicterus or be left with severe neurosensory defects such as spastic choreoathetosis and mental retardation. The remaining fetuses will become hydropic in utero. Half of these will occur prior to 34 weeks of gestational age. Before treatment for Rh alloimmunization was made available, the perinatal mortality rate approximated 50% (7).

## 74.3 DETECTION OF FETOMATERNAL HEMORRHAGE

In the first trimester, fetal cells will be detected in only 3% of normal pregnancies, rising to 12% and 45% in the second and third trimesters and 65% after delivery. Approximately 4% of women will have a transplacental

hemorrhage greater than 0.2 mL following first-trimester termination of pregnancy (8).

The acid elution test of Kleihauer et al. (9) depends on the resistance of fetal hemoglobin to acid elution. After acid elution, staining of a blood smear with eosin will show the fetal erythrocytes as dark cells on a background of white maternal “ghost” cells. The technique will detect as few as one fetal cell per 200,000 maternal cells, and has been used to determine the size and frequency of fetomaternal hemorrhage at different stages of pregnancy. However, since this test relies upon the detection of fetal erythrocytes instead of Rh-positive cells, a reading of up to 2% of cells with fetal hemoglobin can be considered a false positive since it is not abnormal for an adult to circulate 2% of cells with fetal hemoglobin (10).

Therefore, the detection of fetal hemoglobin in maternal circulation does not necessarily imply that a fetomaternal hemorrhage occurred. It has been demonstrated that anywhere from 0.2% to 7% of adult erythrocytes contain hemoglobin F. It is thought that this proportion is genetically determined. One of the drawbacks to the Kleihauer–Betke test is that it is imprecise and can lead to undertreatment as well as overtreatment. In some, undertreatment may explain why some women still develop Rh disease despite the administration of Rh immunoglobulin. With this in mind, more rigorous tests such as flow cytometry should be considered (10).

## 74.4 RH BLOOD GROUP SYSTEM

Individuals are classified as Rh positive or Rh negative, depending on the presence or absence of the major D antigen on the RBC surface. The RhD epitope is the most immunogenic of the Rh system. The next most antigenic, Rhc, is more than 20-fold less potent. For this reason, the terms rhesus positive, Rh positive, and RhD positive have become synonymous in clinical practice. While the introduction of RhD immunoprophylaxis has reduced the incidence of RhD alloimmunization, the incidence of disease due to other antigens is increasing. Furthermore, none of the antigens is present on rhesus monkey erythrocytes.

Two other major antigens, the C/c and E/e series, play important clinical roles. One significant difference between the D and CcEe antigens is that there is no serologically defined “d” antigen. Although hematologists will refer to an individual as DD, Dd, or dd, the designation “d” indicates the absence of the “D” antigen. In the case of Cc and Ee, both the uppercase and lowercase letters indicate the presence of a serologically definable antigen. The genes encoding these three antigens are inherited together. This suggested to earlier investigators that there would be either one single gene encoding all the C/c, D/d, E/e epitopes or three genes closely linked on the chromosome, so that recombination rarely takes place between them. Virtually all normal erythrocytes carry the antithetical antigens C

and/or c and E and/or e. The erythrocytes of individuals who lack these antigens have multiple membrane abnormalities, suggesting that the Rh antigens are key to membrane stability. The RhD-negative phenotype occurs in approximately 15% of the white population. Thirty-five percent of Basques are RhD negative, whereas only 1% of North American Indians and 7% of African-Americans are RhD negative. The incidence in Asiatic Chinese and Japanese is almost zero.

### 74.4.1 Nomenclature of the Rh Antigen System

Theories about the molecular basis of the Rh blood group system have been proposed and then discarded. The Fisher–Race system is based on the original Fisher theory that the Rh gene locus consists of three genes with antithetical alleles C/c, D/d, and E/e. In this scheme each haplotype (i.e. each chromosome) is designated as carrying one of each of the antithetical triplets. For example, the three most common are CDe, cde, and cDE. This simple and relatively straightforward scheme was opposed by Wiener, whose theory suggested that all the Rh alleles are epitopes of a single protein, and therefore, the product of a single gene. In the nomenclature based on this theory, separate terms are used for the whole complex of antigens (so, for example, CDe becomes R1), and for each component factor (Rh0 = D, rh' = C, rh1 = Ce, etc.). Although this terminology is more complex and less specific, and despite a recommendation by WHO in 1977 that it should be abandoned in favor of the Fisher–Race system, it is still widely used by hematologists.

### 74.4.2 Molecular Basis of Rh Antigens

Studies of the molecular basis of the Rh antigens at the protein level were complicated by loss of Rh antigenic reactivity after membrane solubilization or immunoblotting.

Moore et al. (11) and Gahmberg (12) independently identified proteins of 28–32 kDa that could be immunoprecipitated using anti-Rh antibodies. A team led by Cartron at Institut National de Transfusion Sanguine (INTS) in Paris, France virally transformed B cells from donors with circulating Rh antibodies to develop cell lines secreting monoclonal antibodies specific for RhD, c, and E antigens. These monoclonal antibodies allowed the number of Rh antigen sites per cell to be determined. There are approximately 105 Rh antigens to each erythrocyte, with C/c, D, and E each contributing about one-third of the total (13–15). The Rh polypeptides could then be immunopurified by the addition of large quantities of the monoclonal or polyclonal anti-D to erythrocyte membranes that had been surface labeled with 125I (16,17). Rh polypeptides were also isolated from surface-labeled RhD-positive erythrocytes by hydroxyapatite chromatography and electrophoresis of

SDS-solubilized membrane skeleton vesicles (18), leading to a nearly 200-fold purification. From these studies, the total number of Rh polypeptides per erythrocyte was calculated to be approximately 60,000. The 28- to 32-kDa Rh polypeptides were suspected to consist of several species, and one-dimensional SDS polyacrylamide gel electrophoresis showed that there was a small difference in the mobilities of the different polypeptides. The RhD polypeptide migrated with an apparent molecular weight of 31.9 kDa, whereas c and E were 33.1 kDa. When the isolated Rh polypeptides were digested and analyzed by electrophoresis, variations in the degradation patterns indicated that RhD is distinct from the C/c and E/e polypeptides. Antibodies raised to denatured, purified RhD polypeptide were found to cross-react with the Rhc and Rhe polypeptides (19). Digestion of intact erythrocytes with phospholipase A2 and papain caused degradation of the RhD polypeptide but not the RhC/c or -E/e polypeptides (20). These studies, therefore, showed that the Rhc, -D, and -E polypeptides are very similar although each is a distinct protein (21). The c and E polypeptides were found to be nearly identical, whereas the D polypeptide was found to be related but less similar (Figure 74-1).

Almost all our current knowledge of this group of proteins has come from cloning studies of the Rh cDNA. Although antibodies to RhD and other Rh antigens were widely available, they were only specific for the Rh antigens. They were not suitable for the identification of Rh

polypeptides produced from cDNA expression libraries. Oligonucleotide probes for isolating Rh cDNAs were designed from partial amino acid sequence data of the isolated polypeptides. A clone specific for one species of Rh polypeptide was isolated independently in 1990 by the Paris group (22) and a group in Bristol (23), both having used the polymerase chain reaction (PCR) with oligonucleotide primers designed from segments of the N-terminal amino acid sequence to amplify cDNA templates prepared from either thalassemic spleen erythroblasts or peripheral reticulocytes. These PCR products were then hybridized to cDNA libraries to identify specific clones of approximately 1.4 kb. Both groups used the same commercially acquired cDNA library, prepared from the marrow of the same donor. The sequence of the open reading frames reported by each group was identical. The isolated cDNA localized to chromosome 1p34.3–p36.1 by in situ hybridization, which was consistent with previous linkage evidence that localized the RH gene locus to chromosome 1 (24). This first cDNA clone proved to encode both the C/c and E/e proteins. In 1992, the Paris group reported the isolation of the RhD polypeptide cDNA from a cDNA library (25). The coding sequence of this clone exhibited 3.5% divergence at the amino acid level. To confirm that this clone encoded the RhD polypeptide, they demonstrated that its gene was present only in RhD-positive individuals. Restriction fragment length polymorphism analysis of DNA from individuals with

**FIGURE 74-1** The genetic basis of the rhesus blood group system. RhD protein is encoded by a single gene that is deleted on RHD-negative chromosomes. The RhCcEe proteins are encoded by a single gene that is highly homologous to the RHD gene. Translation of a full-length mRNA transcript produces the RhEe polypeptide, which is of similar size and structure to the RhD polypeptide. The RhEe polymorphism is due to a single-point mutation, which changes amino acid 226. RhC polypeptides are produced from smaller splicing isoform transcripts of the same gene and are therefore smaller peptides than their RhD or RhEe counterparts. The RhCc polymorphism is due to four-point mutations, which make four amino acid substitutions. Associated with these substitutions are two further silent point mutations.

RhD-positive and RhD-negative erythrocytes shows that RhD-positive individuals have two Rh polypeptide genes and that RhD-negative individuals have only one (25). It therefore appears that the RH gene locus consists of two highly homologous, closely linked genes, one of which encodes both C/c and E/e proteins. The other gene encodes the RhD protein and is absent in RhD-negative individuals. Rh antigens are expressed on the erythrocyte surface only in the presence of RhAG. Both Rh and RhAG proteins have 12 transmembrane  $\alpha$ -helices through the erythroid cell membrane, joined by six exoloops and five endoloops with N- and C-termini within the cytoplasm (26,27). The Rh accessory proteins form a group of glycoproteins that are associated with the Rh protein family, and together the association is called the “Rh complex.”

The Rh polypeptides are 30-kDa unglycosylated proteins that can undergo reversible palmitoylation. It is likely that they play a fundamental role in the physiology of RBC membranes that is unrelated to their antigenicity. Similar observations have been made in the cases of other blood group antigens that are often functionally important structures. The multiple membrane-spanning domains of the Rh polypeptides suggest a transporter protein, as a channel, an exchanger or a pump, but the function of the polypeptide or the ligand has not yet been conclusively demonstrated. It has recently been postulated that they may have a function similar to methylamine permease (Mep) transporters (28), that they may be related to the superfamily of ammonium transporters (29), and that the Rh glycoproteins function as dual directional ammonium transporters (30). However, the homology is about 20%, the Mep/Amt family of transporter proteins is present in bacteria, yeast, and plants but not in vertebrates, and there are conserved sequences within the Rh family not found in the Mep/Amt family. So, it remains unclear what may be transported across the membrane, if indeed anything at all. The study of uptake and excretion of metabolic molecules such as

ammonium across normal and Rh-null erythrocyte membranes may help elucidate their biological function in mammals.

Erythrocytes from donors of all the common Rh phenotypes are normal, suggesting that the C/c or E/e polymorphisms have no effect on the function of the protein and that erythrocytes can function entirely normally without expression of the D polypeptide. Comparison of distantly related proteins isolated from erythrocytes of several nonhuman species show conservation of the fatty acylation characteristic, suggesting a common functional significance. The membrane defects seen on erythrocytes from individuals with the Rh-null phenotype provide clues to the functional roles of the Rh polypeptides. Rh-null patients have a mild to moderate chronic hemolytic anemia. Rh-null erythrocytes are pleomorphic but always have some degree of stomatocytosis and spherocytosis, and have increased sensitivity to osmotic lysis. Rh-null membranes have characteristically hyperactive membrane ATPases, reduced cation and water contents, and a deficiency in membrane cholesterol (31). Physiologic roles in membrane stability and volume regulation have been suggested for the Rh polypeptides, but specific details have yet to be elucidated.

Certainly, the principal clinical interest in the Rh polypeptides is in their roles as antigens. The RhD protein expresses the D antigen. The RhCE protein expresses both the C (or c) and E (or e) antigens on the same protein, the C/c antigens being present on the second exoloop and the E/e antigens on the fourth exoloop (32,33). Many of the current data on the primary structures of these polypeptides have come from cDNA studies (see previous discussion). They are 417 amino acids long, there being only about 8% difference in the sequence between RhD and RhCE, or by only 30–35 amino acids (Figure 74-2). Despite such homology, the two proteins do not share antigens unless there is hybrid rearrangement between the two genes (34). These antigens appear early during erythropoietic development and early in fetal life.

**FIGURE 74-2** The genetic basis of the RhCcEe polymorphisms. (A) The RhCE proteins are encoded by a single gene, which is highly homologous to RHD. (B) Common RhCE polymorphisms arise from point mutations within RHCE. Single amino acid substitutions (P, proline; S, serine; A, alanine) give rise to the antigenic differences on the exoloops observed between the various isoforms. Numbers start from first methionine residue.

### 74.4.3 Structure, Evolution, and Molecular Diversity of Rh Gene Family

RH genes (RHD, RHCE) are highly homologous and RHAG is a close ancestral cousin. RHD codes for Rh30 proteins carrying the RhD antigen. RHCE codes for Rh30 polypeptides coexpressing the Ce, ce, cE, and CE antigens. Both genes comprise 10 exons encompassing 69kb of DNA. They reside in tandem on chromosome 1 ordered 5'-RHCE-RHD-3' (24,35). The two genes are opposite in orientation (tail-to-tail joining, 3' ends of the genes face each other) (36). RHAG is also composed of 10 exons encompassing 32 kb on chromosome 6, and has a very similar intron-exon structure to the RH genes.

Although initially thought to be erythroid specific and the genetic heritage of higher vertebrates, RHAG

homologs have been found in widely diverse organisms, such as the marine sponge, nematodes, mice, and nonhuman primates. The genetic and phenotypic polymorphism observed within the Rh gene family has arisen from a combination of inter- and intragenic duplication, rearrangement, allelism, and alternative splicing. It is thought that an ancient gene duplication event (250–346 million years ago) diverged RH from RHAG (37). A more recent gene duplication (5–12 million years ago) led to the human RHD and RHCE genes. Primitive organisms have fewer copies of the Rh genes, suggesting that the Rh gene family has expanded through duplication. Variant Rh antigens arise from alterations in the RHD/RHCE (38).

Molecular biodiversity underpins the variety of Rh antigenicity seen within and without ethnic communities. The genetic rearrangements have arisen by whole gene deletion, microconversion or macroconversion events, and antithetical missense mutations. Of all the known variations (and potential variants), the D-negative phenotype is clinically the most important. The loss of D antigenicity can arise from silencing of the D epitope. The incidence of the RhD-negative phenotype (dd) in whites is 15%, the vast majority arising from a total deletion of RHD (36,39). Among the Asian and some African races, other mechanisms, such as replacement of as many as eight of the central exons by RHCE, of point mutations and base pair deletions, are known to act. The incidence of RhD negativity in African-Americans is 7%, and this falls to almost zero among the Asiatic Chinese and Japanese. Although rare and occurring in a population where dd homozygotes are uncommon, knowledge of these alternate mechanisms for D antigen silencing indicates caution when applying a PCR-based diagnosis for prenatal genotyping.

#### 74.4.4 Prenatal Rh Genotyping

The tandem arrangement of the RHD and RHCE genes on chromosome 1 may contribute to the complexity of the Rh blood group. This arrangement may explain the evolution of aberrant RH alleles caused by replacement of RHD or RHCE gene fragments with their counterparts resulting in the formation of RHD-CE-D or RHCE-D-CE alleles. Template mutations caused by gene conversions have also been noted. Single-point mutations have also produced other variants on these genes. These variants have been known to cause problems with genotyping assays. Most of the aberrant RHD alleles code variant RhD polypeptides on which not all RhD epitopes are expressed while causing new Rh antigens to appear. Theoretically, these variants might lead to alloimmunization in Rh-negative mothers. The relative frequency of these mutations is rare.

The significance of these RH alleles for genotyping is that they may increase the false-positive or false-negative results. A fetus, which is Rh negative, may be classified

as Rh positive when the RH-specific PCR assays are performed. It is entirely possible that when a serologically Rh-negative mom is tested, she may test positive because of these aberrant sequences, which in turn may lead to false-positive fetal genotyping.

The fetus of a sensitized RhD-negative mother and a father who is heterozygous for the D antigen has a 50% chance of being RhD positive and at risk of allo-immune intrauterine hemolysis. Prenatal determination of the fetal Rh serotype or genotype will reveal whether the fetus is at risk. A significant benefit of identifying an Rh-negative fetus is that it does not need to be subjected to invasive testing. Much of the development in prenatal Rh genotyping has been focused on finding less-invasive methods to identify the RhD-negative fetus.

#### 74.4.5 Molecular Diagnosis

Until recently one of the two approaches—fetal blood sampling or serial amniocentesis—was used to identify the at-risk RhD-positive fetus where the father is heterozygous RhD positive. Fetal blood sampling for serologic Rh typing has 1–2% risk of fetal loss, and 40% risk of fetomaternal hemorrhage, which may cause Rh sensitization. Serial amniocenteses for quantification of bilirubin in amniotic fluid are less accurate because it is unable to distinguish an RhD-negative fetus from a mildly affected RhD-positive fetus. In addition, it exposes the mother of an RhD-negative fetus to multiple invasive procedures. With each subsequent procedure, the risk of catastrophic sensitization increases. Before the cloning and sequencing of the RhCcEe and RhD cDNAs, prenatal determination of fetal RhD status could be performed only on fetal blood samples or fetal erythrocytes obtained from chorionic villus sampling. The small quantity of fetal erythrocytes obtained from chorionic villus samples makes standard agglutination techniques unreliable. Therefore, immunofluorescence or immunorosette techniques are used (40,41). This approach was not widely adopted because it was time consuming and cumbersome, and because of the risk of false-negative results, where the yield of fetal cells was very low. In addition, chorionic villus sampling causes detectable fetomaternal hemorrhage in half the cases, which, if the fetus is RhD positive, may accelerate hemolytic disease and may lead to fetal death as early as 20 weeks.

Since the cloning of RHCE and RHD, it is now possible to Rh genotype the fetus by PCR using a small amount of its DNA from amniocytes, chorionic villi, and fetal cells/free fetal DNA in the maternal blood. When designing, using, or relying on a PCR-based Rh genotyping, it should be borne in mind that (1) although the majority of RhD-negative individuals have an RHD gene deletion, some RhD variants have diminished or absent antigenicity with intact, albeit altered, RHD; (2) as the prevention of RhD alloimmunization through anti-D immunoprophylaxis programs becomes more effective,

so will Rh alloimmunization due to the other Rh antibodies gain in importance.

The perfect strategy for prenatal determination of fetal RhD genotype would be to design a pair of PCR primers that would amplify a specific region of the RHD gene with no cross-hybridization, with either the RHCE gene or to any other gene. A PCR product would therefore be generated from RhD-positive and not from RhD-negative DNA. To demonstrate that the absence of an RHD-specific product from RhD-negative DNA is not due to laboratory or experimental error, a second control amplification should be performed in duplex with the RHD-specific reaction. Although this could be of any other conserved sequence, it is more elegant to use a sequence specific to the RHCE gene. The principal difficulty in designing RHCE- and RHD-specific PCR primers is the high degree of homology between the RHCE and RHD genes. In exons 1–9, there are isolated nucleotide differences between RHCE and RHD, making the design of specific PCR primers difficult. Exon 10 contains a region of divergence. In this region, there exists a copy of the Alu repeat motif, which is found in a large number of genes and other noncoding sequences.

The first report of the use of PCR for prenatal determination of fetal RhD used RhD-specific primers designed from the 5' end of exon 10 of RHD (16). This primer pair was originally used by the Paris group to demonstrate that their novel RH cDNA encoded the RhD polypeptide. The 5' primer lay within a region of 100% homology between RHCE and RHD. It was the 3' primer, designed to an RHD-specific region, which gave the specificity to the reaction. A control primer pair, designed from sequences in exon 7, amplified a 134-bp product from both RHCE and RHD to act as the experimental control in a duplex reaction. This original report was of 15 cases of amniocentesis, in which the fetal RhD type was also determined by fetal blood sampling. It was followed by a report of the use of prenatal determination of fetal RhD type in six clinical cases (42). Larger studies of the reliability of this system in correctly determining RhD type in a wide range of serotypes using lymphocyte DNA from blood donors were performed by Simsek et al. (43) and Bennett et al. (44). The Simsek group found five discrepancies in 200 cases using the original primers, but was able to correctly predict the RhD serotype in every case using an alternative PCR approach designed by Arce et al. (45). This group had found that the intron between exons 4 and 5 of the RHD is 600 bp smaller than the equivalent intron in RHCE. PCR primers were therefore designed for the 3' end of exon 4 and the 5' end of exon 5 to amplify intron 4, which would generate a 1200-bp product from the RHCE gene and a 600-bp product from the RHD gene. This approach is elegant in that the same pair of primers is designed from both RHD and RHCE genes. Using this primer pair, Simsek et al. (43) were able to correctly predict the RhD serotype in all 200 donors. In a similar study of 248 donors, Bennett

et al. (44) correctly predicted RhD serotype in all cases, using the original exons 7/10 primer sets.

PCR is notorious for its false-positive results caused by contamination, and due care must be taken to eliminate contamination by RhD-positive DNA, which might occur at any point from collection of the sample to performance of the test. However, in a test where the “negative” result so heavily biases management, we must be mindful of false negatives too. In a study of 135 clinical cases, in which fetal RhD type was determined using the original exons 7/10 PCR primers following amniocentesis, Lighten et al. (46) made two errors where RhD-positive fetuses were thought to be RhD negative, resulting in a mild disease in one fetus and hydrops and death in the other. When both fetuses were retested after birth, they were both RhD positive by PCR. Although this represents an error rate of only 1.4%, the consequences of incorrect determination of fetal RhD type, whether due to laboratory error or to genetic variation, can be so great that most workers would now agree that two independent primer sets should be used. This approach has been successfully combined in a single multiplex reaction, and should give clinicians greater confidence in prenatal RhD determination by PCR.

Inaccuracies of prenatal RhD determination may be due not only to experimental error in the PCR but also increasingly importantly to genetic variation at the RH gene locus. Some individuals produce an altered RhD protein (partial D) within their erythrocytes. This comes about by genetic rearrangements within RHD exons. The RBCs of such individuals can induce allo-antibodies in RhD-negative individuals and, conversely, they themselves can make alloanti-D if transfused with RhD-positive erythrocytes. So, as a donor, they must be classed RhD positive; as a recipient, they are RhD negative. A fetus carrying a partial D antigen should be classed as RhD positive, but if the mother is known to have a partial D phenotype, she must be treated as RhD negative with respect to the pregnancy. A fetus with a partial D phenotype appears unlikely to suffer severe intrauterine hemolysis (47). Similarly, mothers with a partial D phenotype alloimmunized to the D antigen appear less likely to severely affect their RhD-positive fetuses (48). With respect to fetal partial D in an RhD-negative mother, however, identifying the presence of RHD is enough, initially, to flag the clinical case as one of potential alloimmunization; prognostication is another matter.

By contrast, in some racial groups (Africans and Asians in particular), it is not enough to identify the presence of RHD as they carry genetic mutations that render an intact RHD nonfunctional. A fetus may have the RHD gene but may, at the same time, be RhD negative and not warrant any further invasive testing. As knowledge and awareness of these variations increase, and as mixed-race couplings and molecular analyses become more common, this group of conditions will gain in importance. Under these circumstances, knowledge of

the ethnic origins of the parents and both their blood group phenotype and genotype will dictate the molecular testing most appropriate for the individual fetus.

**74.4.5.1 Noninvasive Prenatal Diagnosis.** Historically, fetal DNA was obtained from amniocytes obtained via amniocentesis or chorionic villus sampling. Both these techniques are invasive and do carry a risk of spontaneous abortion. The risk of a maternal hemorrhage from these procedures approximates 20%. Because of these risks, a better source of fetal DNA was needed (49). Because RhD-negative individuals are commonly deleted for the RHD gene, it is an attractive possibility that fetal RhD-positive DNA might be detected from within a background of maternal RhD-negative DNA using PCR. Unlike the case with single-gene disorders, where the carrier or affected mother would also have the mutated gene represented in her genome, the RhD-negative maternal DNA should not be a template for PCR, which should only amplify a product if there is fetal RhD-positive DNA present. Free DNA of fetal origin has been shown to circulate in whole maternal blood (17) and the maternal plasma and serum (50), or it can be extracted from the cellular fraction of maternal blood. It was hypothesized that fetal RhD-positive DNA might be detected from any of these fractions, allowing the RhD type of the fetus to be determined without exposing the mother to the risk of invasive procedures.

Approximately 3% of cell-free DNA in the maternal plasma during the first trimester is of fetal origin. As the pregnancy progresses, this figure rises to 6% by the third trimester (49). Free fetal DNA has been detected as early as 4 weeks of gestational age (49). Cell-free DNA in plasma of pregnant women consists of longer fragments than those found in nonpregnant women. Fetal DNA fragments are generally shorter than maternal fragments. Thus, enrichment of the proportion of DNA derived from the fetus is theoretically possible by exploiting these differences in fragment sizes, but complete separation has not been practical. Currently, the only diagnostic tests available on free fetal DNA targets genes which are not present in the mother. Examples include fetal sex determination via a gene present only on the Y-chromosome and detection of fetal blood grouping in women whose erythrocytes lack the target antigen (7).

Lo et al. (51) first described the use of PCR to identify fetal RhD type from maternal blood without any prior attempt to separate the fetal from the maternal cells. Using a slightly longer version of the original Cartron exon 10 primers in a heminested reaction, they were able to detect RhD-positive DNA in pregnancies where the fetus was RhD positive and the mother was RhD negative. There was, however, an unacceptable false-positive rate which may be secondary to the fact that the concentration of fetal DNA in maternal plasma is very low (7). Over time, this was improved upon by stricter anti-contamination measures (52) and the use of real-time fluorogenic PCR analysis (53). Recently, the same group

published an important clinical paper (54), in which they studied 57 RhD-negative pregnant women, 12 in their first trimester of pregnancy, 30 in their second trimester, and 15 in their third trimester. Thirty-nine fetuses were RhD positive and 18 were RhD negative. In the samples obtained from women in their first trimester, two contained no RhD DNA but the fetuses were RhD positive; the results in the other 10 samples were concordant (seven were RhD positive and three RhD negative). However, among the maternal plasma samples collected in the second and third trimesters of pregnancy, the results of RhD PCR analysis of maternal plasma DNA were completely concordant with the results of serologic analysis of the fetus. It is unclear from this report, however, how many of the 47 multigravidae in their cohort were already sensitized to the D antigen. This will have a bearing on the overall efficacy of this test as their earlier work suggested the possibility of enhanced clearance in sensitized mothers (55).

Fetal Rh genotyping using cell-free fetal DNA circulating in maternal plasma appears to be the most cost effective and readily acceptable for clinical practice (56). The methods which have been shown to be reliable for determining the D phenotype from fetal DNA in maternal plasma use real-time quantitative PCR with Taqman chemistry. These primers and probes detect exons 4, 5, and 10 of RHD but not RHCE (7). Some authors have cautioned premature reliance on this technology (57,58). However, others such as Finning et al. show 100% accuracy in fetal RhD genotyping from maternal blood (59). This has led to the introduction of this test into clinical practice since May 2001, at the International Blood Group Reference Laboratory (IBGRL) in Bristol, UK. Using currently to predict the fetal RhD status in allo-immunized women, the group is expanding its research focus to study mass-testing of plasma from all D-negative pregnant women (60). The usefulness of cell-free fetal DNA for determining the fetal RH genotype has been confirmed by the demonstration that fetal Rh D, C, c, and E genotypes can now all be predicted from maternal plasma (61).

**74.4.5.2 Preimplantation Genetic Diagnosis.** A subgroup of sensitized RhD-negative women with heterozygous RhD-positive partners, who have experienced repeated pregnancy losses or serial intrauterine transfusions in previous pregnancies, are unable to cope with psychological stress of future affected pregnancies. For these patients, preimplantation determination of embryonic RhD type after in vitro fertilization and before embryo transfer would allow RhD-positive pregnancies to be avoided in the future. To perform molecular diagnosis of the RhD blood type from the DNA present in a single human diploid cell, DNA amplification by “nested PCR” is required. This consists of two rounds of amplification. First, a low number of cycles is used with an “outer” set of oligonucleotide primers. The second PCR is then performed on a small aliquot from the first

reaction, using a higher number of amplification cycles with primers internally nested to those in the first reaction. This increases both the specificity and efficiency of the PCR. A primer pair for the outer reaction common to both RHD and RHCE genes within exon 7 was created (62). To account for a single-base-pair difference between the two genes in the region of the 5' primer, this oligonucleotide was synthesized with a single "redundancy" and so consisted of a mixture of two molecules. The use of a common primer pair rather than two sets of primers for "duplex PCR" in the outer reaction of the nested PCR reduces the incidence of inconsistent locus-specific amplification. To differentiate the two genes, an inner reaction was used, taking advantage of four oligonucleotide differences between the two amplified fragments. One inner primer pair was designed to anneal perfectly to the RHD sequence, and a second primer pair annealed perfectly to the RHCE sequence at different but overlapping sites, producing an amplification product of a different size from that of the RHD gene. This strategy, similar to the competitive oligonucleotide priming (COP) PCR used for allele-specific amplification at a single locus, should eliminate the risk that an RhD-positive embryo would be missed.

Numerous other minor antigens are found on the fetal erythrocyte surfaces. These will increase in incidence as RhD alloimmunization become less frequent due to anti-D prophylaxis. Examples of these antibodies known to cause hemolytic disease in the newborn include anti-c, anti-E, anti-Kell, and anti-Duffy. Interestingly, alloimmunization can occur not only against fetal red cell antigens, but also against fetal platelet antigens. Alloimmune thrombocytopenia (AITP) can cause significant fetal morbidity, and is covered in detail in the following section.

## 74.5 ALLOIMMUNE THROMBOCYTOPENIA

AITP is analogous to rhesus alloimmunization, but in this case, the mother produces IgG class antibodies that cross the placenta and affect fetal platelets, leading to thrombocytopenia, and a risk of both antenatal and intrapartum hemorrhage. AITP occurs in approximately 1:350–1:1000 (63). AITP carries the risk of severe hemorrhage, with intracranial bleeding occurring spontaneously in utero in as many as 20% of cases. Neonatal mortality occurs in 1–7% of affected infants. Those who survive are at risk for severe neurological sequelae. These sequelae include mental retardation, cerebral palsy, cortical blindness, and seizures (63). Cases are therefore discovered antenatally when ultrasound identifies signs of intracranial bleeding, or at the birth of an already affected infant. Maternal platelet antibody typing is not performed routinely as part of antenatal care, so women at risk are only identified when they have an affected fetus. Given that screening is not routinely performed,

antenatal treatment is usually provided for those with an affected child. Various in utero treatments have been attempted, including intravenous  $\gamma$ -globulin or steroids and fetal platelet transfusions. However, recent data has demonstrated that intravenous immunoglobulin (IVIG) treatment without invasive testing has been shown to be safe and effective, at least for those with a previous affected child (49).

Platelet alloantigens are located on the glycoproteins on platelet membranes. Conventionally, these antigens are named according to the International Platelet Antigen Working Party nomenclature (64): human platelet alloantigens (HPA), their chronological numbering based on the order of their discovery. Letters "a" and "b" are assigned to the high- and low-frequency alleles, respectively. Excluding alloantigens that are limited to single families and those where only one allele has been identified so far, five platelet alloantigens have been identified to date. HPA-1 and HPA-4 are both epitopes represented on the platelet glycoprotein IIIa, HPA-2 is present on glycoprotein Ib, HPA-3 is represented on platelet glycoprotein IIb, and the weakly antigenic HPA-5 is expressed on platelet glycoprotein Ia.

The molecular basis of HPA-1–5 has been identified and, in each case, is due to a single-nucleotide substitution leading to a single amino acid change in the glycoprotein. The platelet membrane protein GPIIIa gene, which carries the HPA-1 (and HPA-4) polymorphism, was cloned in 1989. The HPA-1b allele differs from the HPA-1a allele by having a C–T substitution at nucleic acid position 196 of the cDNA. This replaces the amino acid leucine in the HPA-1a protein with proline in the HPA-1b isoform. This change also creates a recognition site for the restriction endonuclease Nci I, which has been used as the basis for HPA-1 typing of adults. PCR primers have been designed that span the polymorphic site. The 170-bp products from both HPA-1a and HPA-1b DNA are indistinguishable. To differentiate them, digestion with Nci I is performed, which cuts HPA-1b DNA into two smaller fragments of 106 and 64 bp. A single 170-bp fragment after Nci I digestion indicates an HPA-1a homozygote, and two smaller fragments of 106 and 64 bp indicates an HPA-1b homozygote. A mixture of three fragments indicates a heterozygote. If, however, the restriction enzyme partially digests the target DNA, an HPA-1b homozygote (phenotypically HPA-1a negative) may be incorrectly typed as HPA-1a/b heterozygote (phenotypically HPA-1a positive). An alternative strategy is hybridization of PCR products to allele-specific oligonucleotide probes (44). These are short, single-stranded DNA molecules that are complementary to the polymorphic site. One perfectly matches the HPA-1a DNA; the other contains the C–T substitution and, therefore, matches the HPA-1b DNA. The hybridization conditions are optimized such that only the oligonucleotide with 100% matching will hybridize to the PCR product. Oligonucleotide A will only hybridize to HPA-1a

homozygotes, oligonucleotide B will only hybridize to HPA-1b homozygotes, and both oligonucleotides will hybridize to heterozygote DNA. Each of the polymorphisms giving rise to the HPA-2, -3, and -4 also generates restriction polymorphisms, allowing similar methods of diagnosis.

AITP is regarded as the platelet equivalent of Rh hemolytic disease of the newborn, but in fact, there are differences. Most significantly, in over half the cases, AITP presents in the first pregnancy (65), and maternal antibody levels correlate poorly with disease severity (66,67). The maternal alloantibodies are IgG class antibodies, commonly against HPA-1a in whites (55), and associated with HLA-B8, HLA-DR3, and HLA-DR52 (68–70). After crossing the placenta, the fetal platelet-specific IgG antibodies cause platelet destruction and thrombocytopenia.

In an alloimmunized HPA-1a-negative woman with a heterozygous partner, there is a 50% chance that the fetus will be unaffected. Fetal genotyping by molecular techniques is now possible using amniocytes, chorionic villi, and single cells of blastomeres (71–74).

## 74.6 MANAGEMENT OF ALLOIMMUNIZATION

Prevention is by far the most important aspect of management, because sensitization, or active (as opposed to passive) immunization, triggers the immunologic memory and leads to lifelong alloimmunization.

### 74.6.1 Prevention

Prevention of alloimmunization can be achieved as follows:

- (1) Preventing conception of a fetus with target antigens, either by cessation of reproduction or by selecting sperm from men negative for the offending antigens. The latter could be a social process, for example, changing partners, or a medical one, that is, donor insemination. Neither of these methods has proved to be effective or popular.
- (2) Preventing implantation of embryos positive for the antigen. This has become possible with preimplantation diagnosis.
- (3) Preventing sensitization to the RhD antigen by passive immunization with human anti-D immunoglobulin. The large-scale introduction of this in 1968–1970, following the pioneering work of the Liverpool group (75) and others, has led to a dramatic fall in fetal and perinatal deaths from this cause; it has been a major success in public health.

All pregnant women should be blood-typed and investigated for atypical antibodies in early pregnancy, preferably at the initial prenatal visit. Those who are RhD negative and anti-D negative are at risk of being

sensitized by fetomaternal hemorrhage if the fetus is RhD positive, and this risk is highest at delivery. Patients, who are weak rhesus positive, are not at risk for rhesus alloimmunization and do not require rhesus immunoglobulin. For those who are positive and require it, anti-D given intramuscularly within 72 h of delivery prevents 90% of cases of alloimmunization (75). In the United Kingdom, 100 µg is given, whereas in the United States and elsewhere, 250–300 µg is recommended. The 100 µg dose prevents immunization by up to 4–5 mL RhD-positive RBCs, that is, about 99% of all fetomaternal hemorrhages. At delivery, maternal blood is Kleihauer tested to estimate the volume of fetomaternal hemorrhage, but some consider this unnecessary if 250–300 µg anti-D are given. However, 0.2% of women have fetomaternal hemorrhages larger than 15 mL RBCs, and these would not receive an adequate dose of anti-D and be at risk of sensitization.

Fetomaternal hemorrhage can also be caused by any other events producing placental separation, for example, threatened or complete miscarriage, termination of pregnancy, ectopic pregnancy, antepartum hemorrhage, external cephalic version, abdominal trauma, and invasive procedures such as amniocentesis (76) and particularly chorion villus sampling (77). Women should receive prophylactic anti-D on these occasions, the dose in the United Kingdom being 50 µg before 20 weeks' gestation and 100 µg after 20 weeks (78).

Despite these measures RhD immunization still occurs, probably as a result of spontaneous fetomaternal hemorrhages. Many centers now give routine antenatal prophylaxis of 100 µg anti-D to all nonimmunized RhD-negative women at 28 weeks gestation, as well as at delivery. The American Association of Blood Banks recommends that a repeat antibody screen be obtained prior to the administration of antenatal rhesus immunoglobulin at 28 weeks. Maternal sensitization can occur by 28 weeks. An opportunity to detect hemolytic disease may be missed if such a screen is not performed. A small number of RhD immunizations will continue to occur, as well as those such as anti-c or anti-Kell, which are not preventable. For these patients, methods of treatment must be maintained and improved.

### 74.6.2 Treatment

**74.6.2.1 Red Blood Cells.** A variety of treatment strategies have been developed, both ante- and postnatally. The relatively nonspecific postnatal treatments were the first to be used and are still very important. Early delivery removes the fetus from the adverse environment containing the hostile maternal antibodies. However, this increases the risks due to prematurity, and therefore, the need for neonatal intensive care, which has seen major advances in the past 30 years. Exchange transfusion was one of the most important developments. Its aims are threefold: (1) to lower the unconjugated bilirubin level

and prevent kernicterus, (2) to wash out the maternally derived anti-D and reduce further hemolysis, and (3) to treat anemia by replacing RhD-positive RBCs with RhD-negative RBCs, which will not be hemolyzed. Phototherapy is also a means of lowering unconjugated bilirubin and reduces the need for exchange transfusion.

Postnatal management reduces mortality and morbidity, such as kernicterus, but has complications. Furthermore, the severely affected fetus that might die in utero before a reasonable chance of extrauterine survival, for example, at about 28 weeks' gestation, still requires treatment. Methods of antenatal treatment are needed for these fetuses to help them survive in utero, preferably until they are mature enough for a complication-free postnatal course.

Neutralization of maternal antibodies, or "desensitization," has been attempted by using Rh haptens and RhD-positive RBC membranes. Results have been inconsistent, but on the whole disappointing (79) and none of these methods has entered clinical practice. Maternal anti-RhD antibody levels can be reduced by plasmapheresis, and this has been used in some centers (80), but there is no good evidence that it is effective in improving severe alloimmunization.

Several methods have been used to prevent or modify fetal hemolysis. Corticosteroids and promethazine hydrochloride have been shown to lack beneficial effect. Therapeutic success has been claimed for high-dose maternal intravenous IgG infusions (81). As yet, there are no randomized controlled trials and good results have not been reproduced in other centers. This treatment also has the disadvantage of being extremely expensive.

Fetal RBC production is enormously increased in severe alloimmunization, but in theory, it could be limited by a deficiency in hematinics. Supplementation could therefore improve the erythropoietic response, but a study of the administration of vitamin B12 and folic acid did not result in improved outcome (82). Furthermore, hydropic fetuses do not seem to be deficient in vitamin B12 or folic acid (Rodeck and Nicolaides, unpublished observations). Erythropoietin has been used to manage several types of anemia by increasing RBC production, but it has not been tried in fetal hemolytic disease. As fetal erythropoietin levels are already high, it is unlikely to be successful.

Another approach to the treatment of alloimmune hemolysis is to replace the fetuses' RhD-positive RBCs by transplanting, in utero, RhD-negative erythropoietic stem cells. In theory, transplantation at a gestational age before the development of fetal immune competence, thought to occur at 14–18 weeks, could lead to the induction of tolerance and a state of stable erythropoietic chimerism. The fetus should then have a population of RhD-negative RBCs that would not be destroyed and would prevent death from severe anemia. This has been attempted by giving RhD-negative bone marrow cells into the fetal peritoneal cavity between 12 and 16 weeks

(82) and intravascularly by fetoscopy at 17 weeks into the umbilical vein (83), but without success.

By far, the most successful in utero treatment of severe Rh alloimmunization has been fetal transfusion of RhD-negative RBCs. Fetal anemia can be indirectly assessed by ultrasonography and Doppler examination, less indirectly by amniotic fluid analysis for bilirubin content (84), and directly by fetal blood sampling. Intrauterine therapy is indicated when fetal blood sampling shows that the fetal hematocrit is low or if there is hydrops fetalis. The red-cell transfusion can be administered intraperitoneally, or preferably intravascularly.

The fetal peritoneal cavity was the most widely used route for almost 20 years (85). It relies on the donor red cells being absorbed into the fetal circulation via the subdiaphragmatic lymphatics and the thoracic duct. However, the most severely affected fetuses, with ascites, were not able to absorb the blood and benefited least (86). A significant advantage of this technique is that fetal hemoglobin levels can be obtained before and after the transfusion. The volume of blood needed for transfusion can be calculated using the pretransfusion hematocrit, estimated fetoplacental volume, and the hematocrit of the donor blood (87). Another advantage is that it can be used at very early gestations, is unhampered by fetal lie and position, and can be combined with intravascular transfusion for an extended therapeutic effect (88–90).

In comparison to intraperitoneal transfusion, intravascular transfusion is more successful at reversing hydrops given that hydrops reduces the ability of the lymphatic system to absorb RBCs. Intravascular transfusion was attempted in a few cases in the 1960s by cannulating fetal vessels after exposure by laparotomy. The fetal mortality and maternal morbidity of these procedures were prohibitive, and fetal intravascular transfusion did not become a therapeutic reality until the fetoscope was used (91). The umbilical vein, at either the placental insertion of the cord (92) or its intrahepatic part (93,94), is the preferred target. The donor blood should be fresh (less than 24 h old) O RhD-negative adult blood, screened for transmissible infectious agents, cross-matched with the mother's blood, white cell depleted and packed to a hematocrit of approximately 80% to minimize the volume of donor blood that must be transfused. The volume to be transfused depends on the pretransfusion fetal hematocrit, donor blood hematocrit, and the estimated fetoplacental blood volume (92). The first repeat transfusion usually occurs within a fortnight, and subsequent transfusions are scheduled based on the rate of fall of the fetal hematocrit.

In experienced centers, the fetal/neonatal survival rate should be 90–95%. Intrauterine transfusion is generally considered a safe procedure. However, some complications do occur. The most common complication is fetal bradycardia. Fetal distress may occur secondary to cord accidents (cord rupture, spasm, tamponade (from a hematoma)), or hemorrhage from the puncture site.

Other complications can include preterm rupture of membranes or preterm labor (87). Neonates treated with intrauterine transfusions still need intensive care postnatally. In one series, neonates with Rh disease treated with intrauterine transfusions required less phototherapy but required more top-up blood transfusions. The effect of intrauterine RBC transfusion on the length of phototherapy is most likely due to the fact that less hemolysis occurs because fetal erythrocytes are replaced by adult (donor) erythrocytes, which are less likely to hemolyze. The increased need for top-up transfusions postnatally may be due to decreased erythropoiesis secondary to the intrauterine transfusions (95). Indeed, the management of the neonate is much easier because they are usually delivered at about 37 weeks, and the need for exchange transfusion is minimal owing to the presence of 100% RhD-negative cells, suppression of endogenous RhD-positive cells, insignificant hemolysis, and only minor degrees of hyperbilirubinemia.

**74.6.2.2 Platelets.** Passive prevention of platelet alloimmunization, as for RhD, is not possible. The management of an affected neonate includes IVIG treatment, and the use of washed maternal/donor platelets. In contrast, the antenatal management of AITP is less clear.

If platelet antibodies are detected in a current pregnancy, it is not clear whether the fetus will be affected and require treatment. Nearly 50% of clinically significant cases of AITP are diagnosed during the first pregnancy (96). Pregnant women who have previously given birth to an affected infant with intracranial hemorrhage have a high risk of recurrence, but the majority of at-risk fetuses have siblings with a history of severe thrombocytopenia but without internal bleeding. It is difficult to assess the risk of intracranial hemorrhage to the fetus, so early invasive testing may have to be considered to obtain a fetal platelet count (97,98), or to group the fetus if the father is heterozygous (99). Rarely, platelet alloimmunization may be present in a first-affected pregnancy with fetal hydrocephalus due to intracranial hemorrhage caused by severe thrombocytopenia (100).

The optimal treatment for a patient with a severely affected fetus is controversial. Noninvasive therapies aimed at treating the fetus, such as high-dose maternal intravenous IgG and/or steroids, or both, are of uncertain efficacy (6,55,66,101). On the other hand, invasive treatment, such as fetal platelet transfusion, is of unquestionable efficacy but carries considerable risk because the short half-life of platelets means that frequent transfusions (every 7–10 days) are required (102). The main concern with fetal platelet transfusion is the fetal loss rate, particularly from exsanguination in the presence of severe thrombocytopenia. In one series involving 12 patients, the procedure-related fetal loss rate was 1.2% but per pregnancy, the rate was 8.3% (96). Because of the small numbers of patients seen at each center, multicenter collaboration will be necessary to evaluate different treatment protocols. In the meantime,

preimplantation diagnosis may also become a possibility for these patients (103).

## Biography

**Dr Lau** graduated from the University of Arizona with a Bachelor's degree in Molecular and Cellular Biology (with Honors). He attended the University of Arizona College of Medicine. During that time, he was commissioned as an Ensign in the United States Navy Reserve. He completed an Internship in Ob/GYN at Naval Medical Center San Diego. Prior to internship, he was commissioned as a Lieutenant in the United States Navy. He completed his residency at the Uniformed Services Residency in Obstetrics and Gynecology (National Naval Medical Center and Walter Reed Army Medical Center). He served a tour of duty as an OB/GYN at Naval Hospital Camp Lejeune (North Carolina). Subsequently, his next tour was at Naval Hospital Lemoore (California) where he served as Department Chair. He was awarded the Navy and Marine Corps Commendation Medal (two awards) as well as the Army Commendation Medal. In addition, he has served as a representative to the Patient Safety and Quality Improvement at the American Congress of Obstetrics and Gynecology. He is now completing a Maternal Fetal Medicine Fellowship at Cedars-Sinai Medical Center. His research interests include the use of ultrasound in first trimester fetal diagnosis as well as means of improving patient safety and satisfaction during labor and delivery.

### 75.1 INTRODUCTION

Hematologic malignancies, such as leukemia and lymphoma, are cancers of the blood producing cells. Although in rare cases associated with an inherited mutation and a genetic syndrome such as Fanconi anemia, Bloom syndrome, or ataxia–telangiectasia (AT), these disorders usually occur as sporadic cancers. In other words, they arise from a mutation in a previously normal somatic cell. Leukemia and lymphoma are not genetic diseases in the classic sense, but nonetheless can be called genetic diseases as the primary underlying etiology has been shown to be a DNA mutation, especially chromosomal rearrangements.

Normal hematopoiesis is a highly regulated differentiation and maturation process from a hematopoietic progenitor stem cell to a highly specialized cell of myeloid or lymphoid lineage. If an aberration in the regulatory pathways confers a proliferative advantage to a mutant cell, the end result may be the clinical presentation of leukemia or lymphoma. Leukemia is characterized by a progressive expansion of immature myeloid or lymphoid cells in the bone marrow, whereas lymphoma is featured by an abnormal lymphoid proliferation commonly in lymph nodes, but also in the spleen, tonsils, or skin. In the earlier classifications, such as the French–American–British cooperative Group (FAB classification) in leukemia, and the European and American classification of lymphoid neoplasm (REAL) (1,2), hematopoietic malignancies were classified based on the morphologic features of the abnormal cell population in combination with the clinical presentation. With the expanding knowledge of oncogenesis, in particular the genetic mechanisms in leukemia and lymphoma, the World Health Organization (WHO) developed and revised a universally accepted

classification system of myeloid and lymphoid neoplasms in 2001 and 2008, respectively (3,4), according to the lineage of cell origin and the combination of morphologic, immunophenotypic, genetic, and clinical criteria. Many new entities of myeloid and lymphoid leukemia and lymphoma, with unique genetic background and clinical features have been included to define disease entities of clinical significance. The 2008 WHO classification consists of five major groups of myeloid leukemia and six types of tumors of the lymphoid tissues. Genetic abnormalities play an important role as diagnostic criteria for further sub-classification of some neoplasms, in particular of acute myeloid leukemia (AML) (for a detailed classification, see References (4–6)). The new classification defines individual disease groups with a homogenous genetic background and clinical relevance.

### 75.2 GENERAL PATTERNS OF CHROMOSOME ABERRATIONS AND GENOMIC ABNORMALITIES IN LEUKEMIA AND LYMPHOMA

Cytogenetic evaluation of cells from patients with hematologic malignancies has resulted in major advances in our understanding of the specificity of some of the abnormalities observed in tumor cells (7). Chromosomal abnormalities in cancer are non-random and acquired somatic mutations. They occur in the tumor cells only, and represent clonal abnormalities. These abnormalities are not detected when cancer cells are killed and patients go into complete remission; however, they will reappear in relapse. Balanced or unbalanced chromosome translocations, inversion and insertion, loss and gain of chromosomes, and deletions and

amplifications of parts of chromosomes are the common forms of chromosome abnormalities in cancer. The incidence of chromosome abnormalities varies based on disease status and types, from 10 to 25% in low-grade myelodysplastic syndrome (MDS) and myeloproliferative neoplasm (MPN) to 100% in chronic myeloid leukemia (CML) (by definition) (8–10). Balanced chromosome translocations are common in de novo acute myeloid and lymphoid leukemia, and in lymphoma, whereas losses or gains of chromosome materials are frequent in de novo MDS and in therapy-related MDS and AML. In lymphoid leukemia and lymphoma, chromosome translocations, such as t(8;14) in Burkitt leukemia and lymphoma, and t(7;11) in T-cell leukemia and lymphoma, usually result in the conjunction of the promoters and enhancers of the immunoglobulin and T-cell receptor genes with an oncogene or anti-apoptosis gene, leading to a deregulation (i.e., over-expression) of an intact onco-protein (7,11). In myeloid leukemia, and some lymphoid leukemia, that is, acute lymphoblastic leukemia (ALL), chromosome translocation, and insertion or inversion, such as t(8;21) in AML and t(9;22) in CML, result in novel chimeric fusion genes with novel or aberrant function. Chromosome translocation and/or inversion in myeloid and lymphoid leukemia and lymphoma frequently involve the genes that are functionally related to transcriptional regulation, cell cycling, apoptosis regulation, and cytokine signaling pathways (12,13). Loss or deletion of chromosome material may lead to the loss of relevant tumor suppressor genes, whereas gain or duplication are associated with amplification of oncogenes, sometimes in the form of heterogeneous staining regions or double minutes.

Recently, using array comparative genomic hybridization (CGH) and genomic microarray techniques, additional genomic abnormalities have been discovered in almost all leukemia and lymphoma samples analyzed (14,15). Genomic imbalances detected by array techniques are usually subtle and even cryptic, below the sensitivity of conventional cytogenetic analysis. In particular, microarray studies have identified novel genomic aberrations, such as copy-neutral loss of heterozygosity (CN-LOH) in various leukemia and lymphoma with normal karyotypes, and thus have provided new genetic markers for clinical usage and cancer research, because these subtle chromosome lesions commonly contain one or a few critical genes, such as oncogenes and tumor suppression genes that are involved in leukemogenesis and lymphomagenesis (16). Newer techniques, such as next-generation sequencing of leukemia samples will facilitate further delineation of the genetic mechanisms that lead to leukemia and lymphoma.

### 75.3 SIGNIFICANCE OF DETECTING ACQUIRED CHROMOSOME AND GENE ABNORMALITIES IN LEUKEMIA AND LYMPHOMA

Chromosome abnormalities and somatic gene mutations are the hallmarks of many leukemia and lymphoma, such

as the t(9;22) in CML and t(8;14) in Burkitt leukemia and lymphoma. The close association of specific chromosome abnormalities with particular types of human leukemia and lymphoma has been well established in the past several decades, and are very helpful in confirming the diagnosis (17). For instance, the detection of t(9;22) by cytogenetic, or fluorescence in situ hybridization (FISH) analysis will enable a precise diagnosis of CML, and will rule out any other MPN, regardless of morphological features in bone marrow specimens (18). In non-Hodgkin lymphoma (NHL), the detection of t(11;14) in lymph nodes, bone marrow, or peripheral blood samples strongly favors mantle cell lymphoma (MCL), rather than chronic lymphocytic leukemia (CLL), despite any unusual morphological or immunophenotypical features of the tumor cells. Because of its unique association with disease, detecting certain chromosome abnormalities greatly helps in selecting appropriate treatment, such as t(15;17) in acute promyelocytic leukemia (APL) and t(9;22) in CML. Once the t(15;17) is detected in APL by cytogenetic, FISH, or PCR techniques, treatment using all-trans retinoic acid (ATRA) will efficiently induce leukemia cells to further differentiate and then apoptose (19). In CML with t(9;22), Imatinib (also called Gleevec) treatment can induce most CML patients into clinical, hematological, cytogenetic, and molecular remission in a short period (20,21). Moreover, chromosome abnormalities are the most significant prognostic factors for patients with acute leukemia and lymphoma. Patients with AML and t(8;21) and inv(16)/t(16;16), involving the alpha and beta subunits, respectively, of the core-binding factor (CBF) have a very favorable prognosis, whereas patients with AML and abnormalities of chromosome 7 or a complex karyotype show a significantly dismal clinical course (8,9,22). Patients with ALL and t(9;22), and patients with NHL and MYC translocations have much more aggressive clinical courses and unfavorable prognosis (23–26). In addition, detecting a clone with a specific chromosome abnormality such as chromosome translocations enables scientists to clone the genes that are involved in leukemo- and lymphomogenesis, which may provide further therapeutic targets.

The value of performing cytogenetic analysis is reflected by the incorporation of genetic information in the 2001 and 2008 WHO classification systems of myeloid and lymphoid neoplasms. With the new classification system, cytogenetic analysis is required in the complete evaluation of a patient with a newly diagnosed or suspected AML (6). Therefore, a cytogenetic evaluation should be performed for every patient with a suspected or confirmed hematological malignant disease to aid in the correct diagnosis of the malignancy and to assess the patient's prognosis. Furthermore, any abnormality noted at the time of diagnosis can be used as a biological marker to monitor the response to therapy or to detect residual disease in follow-up specimens.

## 75.4 APPLICATION OF CYTOGENETIC, FISH, AND MICROARRAY TECHNIQUES IN DIAGNOSIS OF LEUKEMIA AND LYMPHOMA

The principles and methods used for conventional cytogenetic analysis of malignant disease are very similar to those used for constitutional abnormalities, which have been outlined in detail in Chapter 22. Cancer cytogenetic analysis can be performed on almost any tissue with actively dividing (malignant) cells. For leukemia studies the specimen is usually a bone marrow aspirate although a bone biopsy can also be processed successfully. Alternatively, in patients with circulating immature cells, a sample of peripheral blood can be analyzed. For lymphoma studies, the most appropriate tissue is a biopsy of the affected tissue such as lymph node, spleen, or tonsil. However, even when lymphoma cells are extensively present in the bone marrow, cytogenetic evaluation of a bone marrow aspirate rarely proves to be informative for the study of lymphoma, particularly in low-grade B-cell lymphoma, such as follicular lymphoma and CLL (27).

A typical cytogenetic analysis includes the complete analysis of at least 20 banded metaphase cells. However, this may not always be possible and depends on the cellularity, mitotic index, and quality of the specimen. An analysis of fewer than 20 cells is still informative when a clonal abnormality is detected. According to the International System of Human Chromosome Nomenclature (28), a chromosomal abnormality is considered to be clonal if a structural abnormality or gain of a chromosome is identified in two or more cells. Chromosome loss can occur as a technical artifact during metaphase cell preparation; thus, a loss of a chromosome is considered to be clonal when it occurs in three or more cells. Although chromosome analysis has a low resolution and requires dividing cells, and is very labor consuming, it provides a picture of all chromosome abnormalities in a cell, and frequently will detect novel disease-specific chromosome abnormalities.

The field of cytogenetic analysis was significantly advanced through the development of molecular cytogenetics, that is, FISH in the 1980s (29,30). FISH uses a directly or indirectly fluorescence-labeled single-stranded DNA probe that will anneal to the complementary DNA sequences of a target specimen in interphase or metaphase cells affixed to microscope slides. The source of these tumor cells can be fresh or fixed bone marrow or peripheral blood smears, touch preparations, or paraffin-embedded sectioned tissue. The test probe can be gene or locus specific, chromosome and/or arm-specific, or repetitive sequences specific for individual centromeres or telomeres of each chromosome. FISH can be used not only on metaphase cells but in interphase cells as well, thus enhancing the detection of small non-dividing tumor populations. Moreover, FISH can be simultaneously performed with immunophenotyping techniques

in defining the cell lineages and differentiation of tumor cells with specific chromosome and gene abnormalities. The high sensitivity and specificity of FISH, and the speed with which the technique can be completed have made FISH a powerful tool with numerous applications, such as the detection of numerical and structural chromosomal abnormalities. In many cases, FISH has clarified the nature of chromosomal abnormalities that were ambiguous with banding analysis alone. Using FISH, and the related techniques of multicolor spectral karyotyping (M-FISH or SKY), karyotypic abnormalities can be detected in most leukemia specimens. Nevertheless, FISH is complementary to conventional cytogenetic analysis because it only detects the abnormalities the probes target and hybridize, and it will miss other chromosome abnormalities not targeted by the FISH probes.

The development of CGH and microarray techniques has provided us with more powerful tools to study comprehensive genomic and expression profiling in leukemia and lymphoma at the whole genomic level. The resolution of CGH and microarray is much higher than chromosome analysis in detecting genomic and chromosomal abnormalities leading to copy number alterations in hematological neoplasms. Traditional CGH and array-based CGH use a competitive DNA hybridization of normal and tumor tissues with different-color fluorescence labeling (31). Single nucleotide polymorphism (SNP) microarray can detect genomic imbalances such as loss or gain of gene copy numbers, and CN-LOH, so-called acquired uniparental disomy, due to incomplete chromosome segregation or to mitotic recombination (15). Various cryptic copy number imbalances and CN-LOH have been found in AML, MDS, MPN, ALL, and lymphoma (14,16,32). Novel gene deficiencies have been defined in microarray studies and further characterized by molecular analysis, such as *JAK2* mutations in MPN, *IKZF1* and *PAX5* deletions and mutations in ALL, and *TET2* mutations in MDS and AML (13,33–36). Recently, the application of microarray analysis in leukemia and lymphoma has been extended from basic and translational research to clinical diagnostic laboratories, and certain novel genomic abnormalities discoveries by microarray have been validated to be significant in disease diagnosis and prognosis, and will soon become important new biomarkers in clinical patient care (18,37).

Gene expression profiling analyses by use of microarrays in AML, ALL, MDS, MPN, and lymphoma have provided important information regarding gene expression changes in the pathogenesis of leukemia and lymphoma, and are helpful in the diagnosis and prognosis of lymphoma and leukemia (38). The differences in gene expression profiling can readily distinguish AML from ALL, and can further subgroup diffuse large B-cell lymphomas that have different prognoses and treatment responses (39,40). Gene expression profiling is particularly prognostic in pediatric ALL patients in terms of risk classification and outcome prediction. In combination

with minimal residual disease (MRD) measurement, gene expression profiling helps identify pediatric ALL patients with a higher chance of relapse-free survival. More recently, microRNA expression profiling studies have discovered different microRNA expression patterns in many leukemia and lymphoma, such as AML, ALL, and CLL, and high-grade lymphoma (41–43). MicroRNA expression patterns differ between the normal cells and blast cells, and between AML and ALL, and correlate with cytogenetic abnormalities and molecular markers in AML (44–46). Moreover, microRNA expression in cytogenetically normal AML has been associated with the clinical outcome and with target genes encoding proteins involved in specific innate-immunity pathways (47). The results from microRNA expression profiling are indicative of epigenetic regulation of the targeted genes in leukemia and lymphoma, and are useful in making diagnosis and establishing prognosis (42). Furthermore, microRNA array analysis may highlight novel treatment options by restoring lost tumor suppressor microRNA or silencing highly expressed microRNAs using antagomirs (48).

## 75.5 MYELOPROLIFERATIVE NEOPLASM

### 75.5.1 Chronic Myeloid Leukemia

CML that is characterized by t(9;22) and the *BCR/ABL1* fusion is one of the most common leukemia in adults, characterized by the proliferation of multiple myeloid lineages, and serves as the best model for our understanding of the mechanisms of genetic abnormalities in leukemogenesis (10,49–51). CML was the first cancer in which a unique chromosome abnormality, namely the Philadelphia (Ph) chromosome, was identified (52). It was the second cancer to be associated with a recurring chromosome abnormality, that is, t(9;22), shortly after the t(8;21) was discovered in AML (53,54). CML was also the first disease in which a molecular rearrangement was recognized as resulting in a novel fusion gene and a chimeric protein that was fundamental to leukemogenesis (55–58). Furthermore, CML serves as the first cancer with a rationally designed drug treatment that directly targets the molecular consequence responsible for the pathogenesis of the disease (59). Therefore, CML is a validated research model in cancer biology, normal and abnormal hematopoiesis and lineage commitment, and in targeted drug development and therapy (21,60–62).

The t(9;22) is the hallmark of CML as recognized by the 2008 WHO classification of hematopoietic and lymphoid neoplasms and can be detected by conventional cytogenetic analysis in more than 90% of CML patients (Figure 75-1A) (7,63). It is present in all myeloid lineage cells, including granulocytes, monocytes, erythroid precursors, megakaryocytes, and in all B and some T lymphocytes (64,65). In the remaining 2–10% of the patients with CML, a variant of the t(9;22), such as a

three- or four-way translocation involving a third chromosome or more, can be observed. In a few cases, the t(9;22) is cryptic due to an insertion of the *BCR* gene into the *ABL1* gene or vice versa, which can be confirmed by FISH analysis on metaphase cells or PCR studies (Figure 75-1B). The t(9;22) also is one of the recurring chromosome abnormalities in ALL, particularly in adult patients; the consequence of the t(9;22) is the chimeric mRNA and protein with the fusion between the 3' end of the first exon of the *BCR* gene and the 5' end of the second exon of the *ABL* gene on the derivative chromosome 22 (Ph chromosome) (66,67). The breakpoints in *ABL* are always proximal to the second exon in both CML and ALL, whereas the breakpoints in *BCR* are variably different between CML and ALL. In CML, the breakpoints in *BCR* are more telomeric in the major breakpoint cluster region (micro-bcr (m-bcr), between exons 12 and 15) or m-bcr region (between exons 19 and 21), giving rise to the P210 and P230 fusions, respectively. In contrast, the breakpoints in the *BCR* gene in ALL are far more proximal to exon 2 in a minor breakpoint cluster region (m-bcr), producing the P190 fusion (68). Thus, the location of the breakpoints and the amount of the *BCR* gene that are included in the *BCR/ABL* fusion determine whether the leukemia will be CML or ALL, both showing similar but not identical *BCR/ABL* fusion proteins.

The *ABL* gene is also involved in another translocation, with the *TEL* (*ETV6*) gene on 12p13. *ABL* is a member of the family of non-receptor protein tyrosine kinases, and in its wild-type form it has no transforming activity. Thus, oncogenic transforming properties must be provided by its fusion partners, that is, *BCR* and *TEL*. The *BCR* gene is a member of the Rho family of small GTPases, GAP proteins (69). It is critically involved in activating the *ABL* tyrosine kinase in the *BCR/ABL* fusion protein (70). The first 63 amino acids of *BCR* include a coiled-coil motif, which is able to induce homodimerization and tetramerization of *BCR/ABL*; the *TEL* protein also contains protein dimerization domains. Thus, oligomerization of *ABL* by *BCR* or *TEL* activates the *ABL* tyrosine kinase, induces a microfilament-binding function, and results in transformation. Both p210BCR/*ABL* and p190BCR/*ABL* display deregulated constitutive tyrosine kinase activity; p210BCR/*ABL* is located exclusively in the cytoplasm, where it complexes with various cytoskeletal proteins and constitutively interferes with a variety of cytoplasmic and cytoskeletal signaling pathways. The fusion protein p210BCR/*ABL* is also a powerful anti-apoptotic molecule in mammalian cells, and is directly implicated in the defective responses of both immature and differentiated primary myeloid cells to growth factor deprivation (71,72).

Typically, before the introduction of Imatinib treatment, the chronic phase of CML usually lasted about 3–5 years, and then evolved to an advanced stage. The disease evolution was accompanied in more than 60% of

**FIGURE 75-1** A. Karyotype of a metaphase cell from a male patient with CML in the blast phase. The karyotype is 45, XY, inv(3)(q21q26.2), -7, t(9;22)(q34;q11.2). Gain of additional chromosome aberrations, in addition to t(9;22), is frequently observed in CML during the accelerated and blast phases. B. FISH analysis of cells from the same patient reveals the *BCR/ABL* fusions in metaphase and interphase cells. The probes for *ABL* and *BCR* are labeled with SpectrumOrange® and SpectrumGreen®, respectively. Normal chromosomes 9 and 22 show a single red and green signal, whereas the derivative chromosomes 9 and 22 display a fusion (yellow) signal pattern containing the fused *BCR* and *ABL* probes. Abnormal interphase cells show the typical pattern with two fusion (yellow) and one red and one green signal.

patients with additional chromosome aberrations, which can be reliably identified by cytogenetic analysis in many cases. The most common additions are gain of chromosome 8 (33%), followed by an additional Ph chromosome (30%), i(17q) (20%), +19 (12%), loss of the Y chromosome (8% in males), trisomy 21 (7%), and loss of chromosome 7 (5%) (73,74). They may appear individually or in combination. In certain situations, the appearance of additional abnormalities, such as +8 and i(17q), is a strong indicator of an occult disease progression, often several months earlier than morphological evidence on bone marrow examination or clinical symptoms. Molecular analysis has identified abnormalities of various genes in CML in the accelerated and blast phases (75). These include *TP53* (17p13), *RB1* (13q14), *MYC* (8q24), *p16INK4a* (*CDKN2*) (9p21), and *RAS* (11p15) (75,76). However, it is unclear what chromosome or gene abnormalities are responsible for CML progression.

In the early 1990s, a tyrosine kinase inhibitor, that is, Imatinib was introduced as the frontline drug for CML and has revolutionized the treatment of CML (21). It has significantly improved the outcome of patients with CML, with 97% complete hematologic response and 87% complete cytogenetic remission in a 5-year follow-up study (20). The natural course of CML has now been completely changed because no CML patients with complete cytogenetics remission and an excellent molecular response with more than 3 log reduction of the *BCR/ABL* fusion mRNA has evolved to the accelerated or blast phase during the 5-year Imatinib treatment. Furthermore, novel tyrosine kinase inhibitors, that is, Nilotinib and Dasatinib that have stronger inhibition than Imatinib, have showed significant improvement in patients with resistance to Imatinib treatment (20,77).

In up to 15% of patients with CML on Imatinib, acquired chromosomal abnormalities with no Ph chromosome may appear that either herald disease progression or that may be of unclear clinical significance. The most common clonal abnormalities are +8, -7, -Y, or del(20q) in Ph-negative cells (78,79). The development of new abnormalities has been noted both in patients with prior therapy (IFNa) and in patients treated only with Imatinib (80). Some of these patients had clinical features of a MDS (81,82). Although loss of the Y chromosome is frequently observed in bone marrow cells in elder patients (83), it is likely that the appearance of Ph-negative aberrant clones, particularly -7 and +8, in CML remission after TK inhibitor treatment is a reflection of an early malignant myeloid change at least in some patients; repeating cytogenetic analysis, not just FISH tests at regular intervals (yearly), is warranted to monitor all CML patients in remission (73,84).

### 75.5.2 JAK2 and Other Gene Mutation in Classic Myeloproliferative Neoplasms

In the 2008 WHO classification of leukemia and lymphoma, there are three additional classic MPN diseases, that is, polycythemia vera (PV), essential thrombocythemia (ET), chronic idiopathic myelofibrosis (CIMF), all with features of over-proliferation of one or more myeloid lineages in bone marrow and extra-medullary areas (18). Cytogenetically abnormal clones are present in <5% of ET to >40% in CIMF. Typical abnormalities include del(5q), -7/del(7q), +8, +9, del(11q), del(13q), and del(20q). However, none of these chromosome abnormalities are specific for any of MPN because they are also detected in other myeloid disorders, including MDS and AML.

In 2005, a *JAK2* mutation was identified in these three classic MPN disorders (85–87). *JAK2* belongs to the Janus kinase subfamily and contains a central Src homology 2 (SH2) domain, and two C-terminal domains: a tyrosine kinase domain JH1 (also termed PTK or TyrKc domain) and a tyrosine kinase-like domain JH2 (also termed STYKc). *JAK2* is a protein tyrosine kinase of the non-receptor type that associates with the intracellular domains of cytokine receptors and is the predominant JAK kinase activated in response to several growth factors and cytokines such as IL-3, GM-CSF, and erythropoietin; it has been found to be constitutively associated with the prolactin receptor and is required for responses to gamma interferon (88). The most common *JAK2* mutation is the dominant gain-of-function V617F mutation in the JH2 kinase-like domain. This mutation leads to deregulation of the kinase activity, and thus to constitutive tyrosine phosphorylation activity. The incidence of the *JAK2* mutation is almost 100% in PV, and about 50% in patients with ET and CIMF (5,18). Although *JAK2* mutations are not specific for any of the MPN subgroups and can occur in some patients with MDS with marked thrombocytosis, detecting a *JAK2* mutation helps to prove clonality and to distinguish malignant proliferation from a reactive process. The V617F mutation seems to occur exclusively in hematopoietic malignancies of the myeloid lineage. Other mutations in MPN are *JAK2* exon 12 in PV, *MPL* W515L/K in ET and CIMF, and *TET2* and *ASXL1* (18) (see Section 75.6) in a significant low incidence. In general, these mutations do not seem to be the initial clonogenic event in the development of MPN, and not to correlate with survival or transformation of MPN.

In certain myeloid and lymphoid neoplasms with eosinophilia, abnormalities of the platelet-derived growth factor receptor alpha and beta (*PDGFRA* and *PDGFRB*) genes and fibroblast growth factor receptor 1 (*FGFR1*) have been implicated through various chromosome deletions or translocations, such as t(5;12) (q33;p13), fusing *TEL* (*ETV6*) and *PDGFRB* in chronic myelomonocytic leukemia (CMML), and a cryptic interstitial deletion of the *CHIC2* locus at 4q12, leading to a fusion between *FIP1L1* and *PDGFRA* (65,89) (Table 75-1). Multiple chromosome translocations and deletions have been described in this group with eosinophilia, and some are cryptic and can be detected only by FISH or PCR techniques (Table 75-1). It is important to detect these chromosome abnormalities because patients with *PDGFRA/B* rearrangements are responding well to the treatment with Imatinib and other tyrosine kinase inhibitors.

## 75.6 MYELOYDYSPLASTIC SYNDROMES

The MDS are a heterogeneous group of clonal hematological stem cell disorders characterized by chronic cytopenias, such as anemia, neutropenia, or thrombocytopenia,

and accompanied by abnormal cellular maturation, with an increased risk of development of AML (90). The bone marrow is usually hypercellular due to over-proliferation of myeloid cells, whereas anemia in the peripheral blood is a consequence of inefficient maturation and an early apoptosis (3). Among MDS patients, single or multiple myeloid lineages may be involved, affecting erythroid, granulocytic, or megakaryocytic lineages. The number of blasts in bone marrow and/or peripheral blood samples is variable. In some patients MDS can also develop after cytotoxic chemotherapy and/or radiation therapy for a primary cancer, such as lymphoma, and breast cancer, or after immunosuppression treatment for non-malignant disorders, such as rheumatoid arthritis, or following organ transplantation (6).

Clonal chromosome abnormalities in bone marrow samples can be detected in 40–70% of patients with primary MDS at diagnosis, in up to 90% of therapy-related MDS/AML, and in 100% of MDS with isolated del(5q) which is commonly seen in older female patients with refractory anemia with low blast counts, and normal or elevated platelet counts (90,91). In contrast to AML with the common balanced chromosome translocations, MDS generally shows genomic imbalances, that is, gain or loss of chromosomes and/or chromosome arms (92,93). The most common chromosomal deletion, losses, or gains in primary MDS include del(5q) (25%), -7/del(7q) (20%), +8 (15%), and del(20q) (5%) (Table 75-1) (94–97). As indicated earlier, these common chromosome abnormalities are not specific for MDS as they are also commonly detected in other myeloid disorders, that is, AML and MPN. However, the presence of some of these chromosome abnormalities, along with a refractory anemia, is considered presumptive evidence for MDS, even if there is no morphological evidence of dysplasia in the bone marrow cells (6). Del(5q) and -7/del(7q) (up to 40–50% each) are particularly characteristic in therapy-related MDS associated with alkylating agents and/or radiation therapy (98). Only a few chromosome translocations, for example, t(3;21), inv(3)/t(3;3), t(6;9), and t(11;16) are observed in primary MDS and in therapy-related MDS (t-MDS). Recently, genomic microarray studies have discovered multiple lesions through the whole genome analysis in MDS, including many small cryptic genomic imbalances, such as deletions and duplications, and CN-LOH in low- and high-grade MDS with and without clonal cytogenetic abnormalities. Some of these novel genomic abnormalities detected by microarray in MDS have been implicated in disease progression and the pathobiology of MDS (99–102).

### 75.6.1 Del(5q)

Deletion of the long arm of chromosome 5 [del(5q)] is one of the most common chromosomal abnormalities in MDS, ranging from 10 to 20% in de novo MDS to 40% in t-MDS/AML. An isolated del(5q) has been included in the WHO classification system of MDS to

define the 5q- syndrome which primarily occurs in older females with a very favorable prognosis and an excellent response to treatment with lenalidomide (103–105). In the 5q- syndrome, del(5q) occurs as a single abnormality, whereas it is more frequently included in a complex karyotype in high-grade MDS, such as RAEB. The deletion size of 5q in MDS is variable (106,107). Several genomic mapping studies have showed that deletion of 5q33.1 is uniquely involved in the 5q- syndrome with a good prognosis, whereas a deletion of 5q31 is frequently observed in t-MDS and more aggressive disease (108–110). More than two dozen candidate genes that are located in the critical deletion region on 5q31 were screened for mutations in many primary myeloid leukemia cells. Nevertheless, none of these candidate genes showed any inactivating mutations in the remaining alleles. Thus, it has been proposed that haploinsufficiency or epigenetic regulation in conjunction with del(5q) could be involved in the pathobiology of MDS (111).

Recently, the RPS14 protein that is required for the processing of 18S pre-ribosomal RNA was implied as a candidate gene for the 5q- syndrome through gene expression profiling, knockdown experiments using RNA interference, and forced expression studies (112). Down-regulation of *RPS14* in CD34+ bone marrow cells blocks the differentiation of erythroid cells, and increases apoptosis in differentiating erythroid cells in vitro (113–115). The ribosomal processing defect caused by haploinsufficiency of RPS14 in the 5q- syndrome is highly analogous to the functional ribosomal defect seen in Diamond–Blackfan anemia. It has been shown that loss of *RPS14* cooperates with the haploinsufficiency of microRNAs miR-145 and miR-146a near the *RPS14* gene; both miR-145 and miR-146a are abundant in hematopoietic stem and progenitor cells (116). The Toll-interleukin-1 receptor domain-containing adaptor protein and tumor necrosis factor receptor-associated factor-6 are respective targets of these microRNAs, implying inappropriate activation of innate immune signal pathways in MDS with del(5q).

### 75.6.2 Del(7q)/-7

Deletion of the long arm or loss of a whole chromosome 7 occurs in about 10% of de novo MDS and in up to 50% of t-MDS alone or as part of a complex karyotype (92,98). In many patients with t-MDS/AML, del(7q) or -7 coexist with del(5q). Notably, loss of chromosome 7 is also the most common chromosome abnormality in children with MDS, and in inherent bone marrow failure syndromes. Similar to the status of del(5q), several critical deletion regions were defined in the long arm of chromosome 7, and various candidate genes were analyzed for an inactivating mutations in the remaining alleles; none was positive (117). Patients with abnormalities of chromosome 7 are at high risk of disease progression and have a poor prognosis (97).

### 75.6.3 Trisomy 8

Trisomy 8 is seen in <10% of patients with MDS, often as a part of a complex karyotype. CD34 cells from MDS patients with trisomy 8 express early apoptotic markers but avoid programmed cell death by up-regulation of anti-apoptotic proteins, including MYC and CD1, and thus may result in a selective advantage over normal hematopoietic precursors (118).

### 75.6.4 Del(20q)

Del(20q) of various size occurs in <5% of MDS and is associated with the morphological features of hypogranulated and vacuolized neutrophils and neutrophil erythrophagocytosis (4). Del(20q) is associated with a favorable prognosis if detected as the sole chromosomal abnormality. In chromosome analysis, the del(20q) usually involves a large segment of the long arm (119,120). Genomic SNP microarray analysis defined two common deletion regions of 2.5 and 1.8 Mb at 20q11.23 and 20q13.12, respectively, in a series of MDS patients with a cytogenetic del(20q) (121). Recently, L3MBTL1 polycomb protein, a candidate tumor suppressor located within the critical deletion region on 20q myeloid disorders, has been shown to interact with CDC45, MCM2-7, and PCNA, components of the DNA replication machinery, and is required for normal replication fork progression. Depletion of L3MBTL1 from human cells causes replicative stress, DNA breaks, and activation of the DNA damage response. Thus, haploinsufficiency of L3MBTL1 likely contributes to the development of 20q deletion-associated hematopoietic malignancies, such as MDS, AML, and MPN, by inducing replicative stress, DNA damage, and genomic instability, and by promoting erythroid differentiation (122,123).

### 75.6.5 Prognostic and Diagnostic Significance of Chromosome Abnormalities in MDS

As indicated above, the most common chromosome aberrations in MDS are not specific for any MDS groups; they are also present in other myeloid disorders. However, these chromosome abnormalities are prognostically associated with survival and progression of MDS to AML. The prognostic significance of chromosomal abnormalities in MDS is incorporated into several prognostic scoring systems, such as the International Prognostic Scoring System, the WHO Prognostic Scoring System, and the MD Anderson Cancer Center MDS model (124–128). Patients with a favorable outcome have normal karyotypes, -Y alone, del(5q) alone, or del(20q) alone; those with a poor outcome have complex karyotypes ( $\geq 3$  abnormalities) or chromosome 7 abnormalities, and patients at an intermediate risk have other abnormalities. The median survival times of patients

within these three groups were 3.8, 0.8, and 2.4 years, respectively, and the median intervals for 25% of the patients to undergo evolution to AML were 5.6, 0.9, and 1.6 years (124). In addition, patients with abnormalities involving 3q26.2 and/or over-expression of *EVI1*, and trisomy 11 appear to have a significantly inferior survival (95,129–133). In combination with other clinical and pathological features, detecting chromosome abnormalities provides critical risk-stratification guidelines in deciding appropriate treatment protocols and determining disease prognosis in patients with MDS (130).

The diagnosis of MDS is not always straightforward in some cases. Cytogenetic analysis will provide presumptive evidence in establishing a diagnosis of MDS with detection of certain MDS-related chromosome abnormalities, when patients with refractory cytopenia suspected to have MDS lack diagnostic morphologic features in bone marrow (3,6). These unique chromosome aberrations include unbalanced abnormalities of loss or deletion of chromosome arms in 5q, 7q, 9q, 11q, 12p, 13q, 17p and *idic(Xq)*, and balanced translocations and inversion, such as *t(1;3)*, *t(2;11)*, *t(3;21)*, *inv(3q)*, *t(6;9)*, and *t(11;16)* (Table 75-1) (3). Therefore, all patients with unexplained anemia and pancytopenia should be studied by cytogenetic analysis of bone marrow samples.

### 75.6.6 Gene Mutation in MDS

In addition to the deletions and gains of chromosome material described above, various mutations in several genes, such as *TET2* and *KRAS*, have been detected in MDS. These gene mutations are often related to epigenetic regulation through DNA methylation, histone acetylation, and phosphorylation of tumor suppressor genes and oncogenes. DNA methylation is a mechanism of disease progression to AML and is a prognostic marker and predictor of treatment response in patients with MDS (134,135). In several large series of studies, these gene mutations defined some unique groups of MDS, and were associated with various prognoses. Mutations in *RUNX1*, *TP53*, and *NRAS* are most strongly associated with a poor prognosis, and an increased blast component in bone marrow. Recently, DNA hypomethylating agents that inhibit DNA methyltransferases (DNMTs) have demonstrated activity in MDS and have been incorporated in the initial therapy of many patients with MDS. Together, chromosome abnormalities (particularly deletions) and gene mutations provide insight into the pathobiology of MDS, its progression to AML, and possible new strategies for treatment (102,136,137).

**75.6.6.1 *TET2*.** Ten–eleven translocation (*TET*) family genes encode for proteins that participate in the epigenetic control of DNA expression through demethylation in epigenetic programming, embryonic stem cell maintenance, and early development (138). Somatic mutations, such as frame shift, nonsense, and missense

mutation in *TET2*, occur in 20–25% of myeloid disorders, including MDS, AML, and MPN (37,139,140). *TET2* mutations are particularly common in about 50% of CMML, a mixture of myelodysplastic and myeloproliferative disease with a propensity to progress to AML. Loss-of-function mutations of *TET2* result in increased methylation and silencing of genes that are normally expressed. Recently, mouse model studies have showed that inactivation of *TET2* enhances hematopoietic stem cell (HSC) self-renewal and promotes the development of myeloproliferative disorders (140–142). Inactivation of *Tet2* in mouse perturbs both early and late steps of hematopoiesis including myeloid and lymphoid differentiation in a cell-autonomous manner, endows the cells with competitive advantage, and eventually leads to the development of malignancies. *TET2* mutations are associated with a favorable prognosis in MDS (139). Interestingly, *TET2* mutations can coexist with other pathogenetically relevant mutations in MDS and AML, such as *KIT* D816 V (130).

**75.6.6.2 *RUNX1/AML1*.** *RUNX1/AML1* encodes the DNA binding unit of the heterodimeric CBF that is a critical regulator of definitive hematopoiesis. *RUNX1* mutations, including amplification and point mutations, occur in 10–15% of de novo MDS, and in 15–30% of t-MDS/AML (143,144). Mutations of *RUNX1* are more frequent in high-grade MDS, and often coexist with activating *RAS* mutations, and *-7/del(7q)*. *RUNX1* mutations are associated with poor prognosis and a short overall survival (145).

**75.6.6.3 *TP53*.** The *TP53* tumor suppressor gene encodes an important checkpoint protein that mediates cell cycle arrest in response to cellular stresses and DNA damage. In 10–30% of MDS, *TP53* mutations are present at the time of diagnosis (146,147). Abnormalities in *TP53* are more common in patients with t-MDS (126,148). In addition to various missense mutations in one allele, loss of wild-type *TP53* allele, often seen as a consequence of abnormalities of 17p within a complex karyotype with *del(5q)*, is associated with resistance to treatment and rapid progression to AML, regardless of the IPSS risks score (126,149,150).

**75.6.6.4 *RAS*.** The *RAS* proto-oncogenes, including *HRAS*, *KRAS*, and *NRAS*, play an important role in signal transduction and hematopoiesis (151–154). Mutations of *RAS* have been identified in 10–35% of MDS and AML patients (155). The most common mutations in MDS are in the *NRAS* gene, followed by mutations in *KRAS* and *HRAS*. *RAS* mutations in MDS are associated with loss and deletion of chromosome 7, and with higher incidence of transformation to AML, and a short survival.

**75.6.6.5 *ASXL1*.** The *ASXL1* (additional sex comb-like 1) gene at 20q11.1 belongs to the enhancer of trithorax and polycomb genes that both activate or repress *Hox* genes depending on cellular context. It contains several nuclear receptor binding motifs and

a carboxy-terminal plant homeodomain (PHD) (156). Inactivating mutations involving exon 12 of *ASXL1* are detected in 11–20% of MDS, and in other myeloid disease, such as AML, and MPN (91,157). Most mutations are frameshift mutations and others are missense mutations. *ASXL1* mutations are associated with a shorter overall survival in MDS and a quicker progression to AML (158).

**75.6.6.6 IDH.** Cytosolic and mitochondrial isocitrate dehydrogenases *IDH1* and *IDH2* catalyze oxidative decarboxylation of isocitrate and are involved in cellular defense of oxidative damage (159). Mutations in *IDH1* and *IDH2* oncogenes have recently been reported in 5–15% of MDS and AML (160). *IDH1* mutations are common in AML with mutated *NPM1* without *FLT3* mutations (see below), whereas *IDH2* mutations occur frequently in older patients and are associated with distinctive gene and microRNA expression profiles (159,160). The mutations result in DNA hypermethylation and alteration of gene expression, and are associated with a poor prognosis (161).

## 75.7 ACUTE MYELOID LEUKEMIA DE NOVO

With initial banding analyses, clonal chromosome abnormalities were detected in about 50–80% of patients with AML (7,9). The most frequent abnormalities are translocations t(15;17), t(8;21), inv(16), and a gain of chromosome 8 (Table 75-1). Specific structural rearrangements are closely associated with a particular subtype of AML as defined by the FAB Cooperative Group (FAB classification) (1). For most cases of AML, myeloid blast forms must account for at least 20% of the total cellularity of the bone marrow biopsy sample (4,6). Exceptions to this include leukemia with certain genetic abnormalities or myeloid sarcoma, which are considered diagnostic of AML without regard to the blast count, that is, t(8;21)(q22;q22)/*AML1-ETO*, inv(16)(p13.1q22)/t(16;16)(p13.1;q22)/*CBFB-MYH11*, and t(15;17)(q22;q21.1)/*PML-RARA*. In addition, four more chromosome abnormalities-associated subgroups were defined as AML with balanced chromosome translocations, that is, t(9;11)(p22;q23)/*AF9-MLL*, t(6;9)(p23;q34)/*DEK-NUP214*, inv(3)(q21q26.2)/t(3;3)(q21;q26.2); *RPN1-MDS1/EV11*, and t(1;22)(p13;q13)/*RBM15-MKL1*. These seven subtypes of AML are collectively identified in the 2008 WHO classification system as AML with recurrent genetic abnormalities. In addition, several other rare recurring chromosome translocations are typical in AML, including the t(8;16)(p11;p13) in both de novo and therapy-related AML involving *MOZ*, on chromosome 8 and the *CREBBP* gene at 16p13 (162), and t(8;22)(p11;q13) involving *MOZ* and *p300*. *CREBBP* and *p300* are highly homologous proteins both of which function as histone acetylases (163).

Over 30 recurrent translocations involving 11p15, all involving the *NUP98* gene, have been reported. Twenty-eight partner genes to *NUP98* have been identified including a number of homeobox genes such as *HOXA9* at 7p15, *PMX1* at 1q24, and *HOXD13* at 2q31 (7). Thus, *NUP98*, along with *MLL*, *ETV6* (*TEL*), and *RUNX1/AML1*, is among the rare genes that have numerous genetic partners with vastly different functions (164). Each of these balanced translocations or inversions results in a fusion gene encoding a chimeric protein that participates in leukemogenesis, but is not necessarily sufficient for the development of AML by itself.

### 75.7.1 t(8;21)(q22;q22) and the *AML1/ETO* Fusion

t(8;21)(q22;q22) was first identified in 1972, just before the t(9;22) (54). It occurs in about 8–10% of all karyotypically studied AML and in about 40% of all abnormal patients with acute myeloblastic leukemia with maturation (AML-M2) (8). The t(8;21) is the most frequent abnormality in children with AML, being reported in about 15% of karyotypically abnormal cases (22,153). t(8;21) is often accompanied by the loss of a sex chromosome (in 56%) and del(9q) (in 25%) (165). It results in the juxtaposition of 5' *AML1/RUNX1* and 3' *ETO* (also called *RUNX1T1*), leading to a fusion gene and a fusion or chimeric protein (166,167). The fusion gene is transcribed on the der(8) chromosome from telomere to centromere.

The *AML1* gene belongs to a family of transcription factors with homology to the pair-rule *Drosophila* gene, Runt. The *ETO* gene, also called *Nervy* in *Drosophila* because it is active in the brain, encodes a zinc-finger protein. The fusion gene includes the DNA binding runt homology region of the *AML1* gene and virtually the entire *ETO* gene (168,169). Genomic breakpoints in both *AML1* and *ETO* are clustered in several intron regions and co-localize with topoisomerase II cleavage sites, and DNA hypersensitive sites, implying that these chromatin structural elements are important in the formation of the t(8;21) (170). *AML1* heterodimerizes with the *CBFB* to form a transcription factor, the CBF. The *CBFB* gene is located at 16q22 and involved in the inv(16)/t(16;16). The *AML1/CBFB* transcription factor is critical to hematopoietic stem and progenitor cell growth, differentiation, and function. It binds directly to an enhancer core motif that is present in the transcriptional regulatory regions of a number of genes, including interleukin (*IL*)-3, *GM-CSF*, the *CSF1* receptor, myeloperoxidase, and neutrophil elastase (169,171). Mutant mice with loss of *AML1* or *CBFB* gene function are deficient in hematopoiesis, and die during embryogenesis of intracranial hemorrhage, indicative of the critical role of the *RUNX1/CBFB*-regulated target genes in the development of all blood lineages (171–173).

Transformation by the *AML1/ETO* fusion likely results from transcriptional repression of normal *AML1* target genes via aberrant recruitment of nuclear transcriptional co-repressor complexes to the *ETO* component of the fusion gene (174). Recent studies of the *AML1/ETO* protein fusion showed that it also involves abnormal histone deacetylation, and experiments in cell culture with histone deacetylase (HDAC) inhibitors led to the differentiation of leukemia cells with t(8;21) (175,176). In addition, the *AML1/ETO* fusion protein can directly generate dysplastic hematopoietic progenitors and activate expression of other genes (174). Thus, leukemogenesis by *AML1/ETO* probably results from both altered transcriptional regulation of normal *RUNX1/AML1* target genes and activation of new target genes that block programmed cell death and/or cellular differentiation pathways (174).

The t(8;21) identifies a morphologically and clinically distinct subset of AML (4). The median age in adults is approximately 25 years. The leukemia blasts have features of maturation with Auer rods in pink cytoplasm, and they express CD19 and CD56 in most patients. Clinically, patients with t(8;21) respond well to conventional chemotherapy, in particular to high dose cytarabine treatment, and this leukemia is characterized by a favorable prognosis in both adults and children with the overall 10-year survival of 61 and 80%, respectively (8,9,177). However, gain-of-function mutations of *KIT* involving exons 8 and 17 have recently been detected in AML with t(8;21) and inv(16)/t(16;16), and in mastocytosis, as well as in gastrointestinal stromal tumors and germ cell tumors (178). *KIT* is a member of the type III tyrosine kinase family and encodes a 145-kd transmembrane glycoprotein. Mutations of *KIT* have been shown to have adverse impact on the prognosis of CBF leukemia, with a significantly shorter event-free survival and overall survival rate in patients with *KIT* mutations compared with wild-type *KIT* patients (178).

*AML1* has been shown to be involved with more than 50 other translocation partners, including the t(3;21), which was first identified in CML patients and then in patients with MDS or therapy-related AML/MDS (153). The translocation involves genes at 3q26, *EAP/MDS1/EV11*, in a complex series of alternative fusions (153). Other common partner genes of *AML1* include *MTG16* at 16q24 and *TEL* at 12p13. Except for the fusions with *TEL*, *AML1* provides the 5' part of the fusion and the patients have myeloid leukemia. In contrast, when *TEL* is 5', the leukemia has a lymphoid phenotype (12). In addition, loss-of-function mutations in *AML1* are also responsible for the inherited leukemia syndrome, and familial platelet disorder with propensity to develop AML, and is common in various MPN and MDS (143,144).

### 75.7.2 Inv(16)(p13q22)/t(16;16)(p13;q22) and the CBFB/MYH11 Fusion

The inv(16) and t(16;16) is a clinical cytogenetic rearrangement that results in myelomonocytic (M4)

leukemia with abnormal eosinophils, and is observed in about 7% of newly diagnosed AML (179,180). AML with inv(16)/t(16;16) typically demonstrates monocytic and granulocytic differentiation with abnormal eosinophils in the bone marrow. Arthur and Bloomfield (1983) described a deleted number 16 [del(16)(q22)] in patients whose bone marrow contained an excess of eosinophils (8–54%) (181). We described patients who had M4 leukemia with eosinophils that showed unique morphologic changes, including large and irregular basophilic granules; one-third lacked increased eosinophils because the marrow had fewer than 5% eosinophils (182). In a most comprehensive study to date, inv(16) was observed in 4% of all AML cases where the cytogenetic data were available (8,9). This relatively common (25% of our AML-M4 patients have this aberration) but subtle chromosome aberration was probably undetected in the past, in part because of poor morphology. In children with AML the frequency of inv(16) ranges from 6 to 11%, and is seen in 19–36% of all patients with M4 (22). This chromosome abnormality has clinical implications because the median survival time was more than 65 weeks for AML patients with abnormal 16s, compared to 29 weeks for those with a normal 16 (182). This good response has been confirmed in a number of other studies (8,9,183).

The inversion and/or translocation results in a fusion between the *CBFB* at 16q22 and the myosin heavy-chain gene (*MYH11*) at 16p13 (184–186). Both genes are transcribed from centromere to telomere. The critical fusion is 5' CBFB-3' MYH11. As described earlier, CBFB forms a heterodimer with *AML1*, which directly binds to an enhancer core motif that is present in the transcriptional regulatory regions of a number of genes that are critical to myeloid cell growth, differentiation, and function. It is astonishing that both genes are involved in translocations that are common in AML, although the leukemia cells with t(8;21) and inv(16)/t(16;16) display different morphological features. Eosinophilia is seen in both *AML1/ETO* and *CBFB/MYH11*, suggesting that there may be common pathways that lead to leukemia with the t(8;21) and inv(16) (4). The CBFB protein increases the efficiency of heterodimerization and the affinity of *AML1* binding to DNA. The portion of *AML1* involved in the fusion contains the DNA-binding and heterodimerization motifs. Thus in the t(8;21), the fusion protein contains not only these motifs but also most of the *ETO* protein. Dimerization with CBFB is apparently unaffected. In the inv(16), *CBFB* is fused to *MYH11* creating the *CBFB/SMMHC* fusion protein. *MYH11* also has a dimerization motif; presumably CBFB binds to CBFA2, but it has an additional dimerization partner at the C-terminus binding to *SMMHC*. This *MYH11* protein contains a repeated alpha helical structure involved in myosin filament interactions and may be important in dimerization of the fusion protein in leukemia cells. The *CBFB/MYH11* fusion protein interferes

and represses the function of the CBF transcription factor, and in cooperation with other genetic mutations, such as *c-KIT* and *RAS* mutations, leads to leukemia.

Patients with *inv*(16)/*t*(16;16) have a good response to intensive chemotherapy with a rate of complete remission and 10-year overall survival of 92 and 55%, respectively (8). As described above, gain-of-function mutations of *KIT* will negatively affect on the prognosis of patients with *inv*(16)/*t*(16;16).

### 75.7.3 *t*(15;17)(q22;q12) and the PML/RARA Fusion

A structural rearrangement involving chromosomes 15 and 17 in APL was first recognized in 1977 (187,188). This rearrangement is unique to APL and is the basis for the diagnosis of APL in the WHO classification (3,4,6). The translocation results in a fusion between the *PML* (promyelocytic leukemia) gene on chromosome 15 and the retinoic acid receptor alpha (*RARA*) gene on chromosome 17 (189). The critical junction is located on the *der*(15) and consists of the 5' portion of *PML* fused to virtually the entire *RARA* gene, beginning with the *RARA* response element (190–193).

In the normal situation, *RARA* and retinoic receptor X form a heterodimer that binds to the appropriate DNA RA response elements of target genes. In the absence of ligands, the target genes are in the inactive state and a complex of repression proteins, including nuclear corepressor (NCOR), SIN3, and HDAC, binds to the heterodimer and prevents transcription. Ligands, such as retinoic acid or its derivatives, when present, bind the receptor at physiologic levels and, probably as a result of a conformational change in the heterodimer, displace the repressor complex and recruit transcriptional coactivators, including CREBBP/p300 and SRC1. This leads to transcriptional activation of target genes and differentiation of normal hematopoietic precursors. The *PML/RARA* fusion protein is insensitive to the normal ligands and recruits DNMT enzymes and HDACs to the target site. Transcriptional silencing results from the DNA methylation, hypoacetylation, and recruitment of methyl-CpG binding proteins and NCOR complexes (194,195). The *PML/RARA* fusion protein shows reduced sensitivity to retinoic acid in terms of dissociation of NCOR, a ubiquitous nuclear protein that mediates transcriptional repression. This could lead to persistent transcriptional repression, thereby preventing differentiation of promyelocytes. This effect can be overcome by ATRA, which acts as a ligand for the fusion protein, resulting in release of the HDAC repression complex from the *PML/RARA* fusion protein, with the resultant target gene transcription and maturation and then apoptosis of the APL cells (189,195,196). The fusion protein forms unusual *PML* bodies in the cytoplasm compared with no such bodies with normal *PML*; treatment with ATRA results in normalization of this pattern.

As with other genes discussed, *RARA* is involved in three other translocations with genes *PLZF* (11q23), *NPM1* (5q32), and *NUMA1* (11q13), and with *STAT5B* in a rearrangement within 17q21 (Table 75-1). Recently, a novel translocation *t*(4;17)(q12;q21) was cloned in a patient with JMML, which results in the fusion of the *FIP1L1* and *RARA* gene. These variant translocations are associated with atypical APL. Cells expressing *PLZF/RARA* fusion proteins are not sensitive to ATRA-induced differentiation, although they contain identical *RARA* domains to those of *PML/RARA*. This has been explained by demonstrating that *PLZF* itself functions as a transcriptional repressor through its interaction with the same complex of repression proteins, and this interaction is not affected by ATRA (189,195). Treatment with HDAC inhibitors, however, induces differentiation of *PLZF/RARA* cells in vitro. Therefore, the common mechanism of APL is probably recruitment of HDACs and the transcriptional repression apparatus to the fusion proteins, with the resultant loss of regulation of the target genes.

With the introduction of ATRA for treatment, APL became the first malignancy in which genotype-specific therapy was used. This treatment leads to maturation of leukemic cells in virtually all *t*(15;17) patients, but unfortunately the malignant clone persists and the patients relapse (197). ATRA is combined with cytotoxic drugs to eradicate the leukemic clone. This leads to a remarkable improvement in the overall survival of APL patients. However, patients with some of the variant translocations do not respond to ATRA, and so the precise karyotypic or molecular diagnosis is critical for proper treatment. More recently, treatment in newly diagnosed APL patients with arsenic trioxide (ATO), in combination with ATRA and chemotherapy, achieves an overall survival rate of 91%, in comparison to 60–80% with ATRA and chemotherapy in a 5-year follow-up study (19). Arsenic can directly bind the C3HC4 zinc-finger motif in the RBCC domain of *PML* and *PML-RARA*, resulting in their homodimerization and multimerization with enhanced interaction with the SUMO E2 conjugase Ubc9, facilitating subsequent sumoylation, ubiquitination, and proteasomal degradation (198). Thus, in APL, the combination of ATO and ATRA and chemotherapy has dramatically enhanced therapeutic efficacy and become a frontline treatment option in this otherwise very aggressive disease.

### 75.7.4 11q23 Aberrations and the MLL Gene

The close association of translocations—or, less often, deletions—of the long arm of chromosome 11 (11q) and acute monoblastic leukemia (M5) was observed in multiple studies, especially in children with monoblastic leukemia (199,200). The use of various DNA probes to map the rearrangements of the long arm of chromosome

11 has resulted in the cloning of several different breakpoints in band 11q23, one of which accounts for about 95% of the translocation breakpoints in this band. These translocations have a number of unique clinical features: (1) More than 100 different recurring translocations that involve 11q23, of which 64 partner genes have been cloned in acute leukemia, especially the monoblastic and myelomonocytic types (201). (2) These translocations occur in both myeloid and lymphoid leukemia. The most common translocations in AML are t(9;11), t(6;11), and t(11;19) (q23;p13.1); in ALL they are t(4;11) and t(11;19) (q23;p13.3) (17,202–206). (3) Translocations involving 11q23 have an unusual age distribution, accounting for about three-quarters of the chromosomal abnormalities observed in leukemia cells of infants under 1 year of age. These leukemias are either myelomonocytic or monocytic AML or ALL (207–209). (4) These translocations are seen in leukemias that develop in patients with a primary cancer who previously received treatment with drugs targeting topoisomerase II (206,210,211).

The gene involved in virtually all 11q23 translocations is *MLL*, for myeloid–lymphoid or mixed lineage leukemia (212,213). The *MLL* gene contains regions of homology to the *Drosophila trithorax* gene, especially in the zinc-finger region and the most 3′ segment; as a consequence, it is also called *Htrx*, *HRX*, or *ALL1* (212–214). The breakpoint in *MLL* in virtually all patients occurs in an 8.3-kb breakpoint cluster region just 5′ of the zinc fingers; the conserved junction is on the der(11) chromosome (205). This region contains a number of Alu repeat sequences, as well as one in vivo topoisomerase II cleavage site and an adjacent DNase I hypersensitive site (215–217). By mapping the translocation breakpoints, we and others have shown that in de novo leukemia the breaks appeared to be located preferentially in the 5′ half of the *MLL* breakpoint cluster region, whereas treatment-related leukemias and infant leukemias break more frequently in the 3′ half of the breakpoint cluster, which contains the scaffold attachment region (218). As in *Drosophila*, where the gene is called *trithorax*, *MLL* appears to regulate a number of *HOX* genes, especially in the *HOXA* cluster as well as *MEIS1* by directly binding to promoter sequences (219). These genes, in turn, regulate the expression of genes related to formation of somites during embryonic development, as well as hematopoiesis.

The mechanisms that target *MLL* to specific promoters remain unclear, although at present, we understand some of the functional domains of *MLL*. The *MLL* protein is proteolytically cleaved into two fragments in the cytoplasm (220,221). The N-terminal portion, containing the AT hook domains, the DNMT binding region, and the PHD fingers, functions as a transcriptional repressor through recruitment of HDACs (222). The C-terminal fragment contains the trans-activation domain and the SET domain. When the N-terminal fragment heterodimerizes with the C-terminal fragment

the complex has a transcriptional activation effect. The activation effects are thought to involve histone modifications and chromatin remodeling through recruitment of histone acetyltransferases and by the intrinsic histone methyltransferase, that is, histone H3 lysine 79 (H3K79) activity of the SET domain to interact with multiple *MLL* fusion partners including AF9, ENL, AF10, and AF17 (223–228). At least four groups of *MLL* partner genes with various putative functions have been identified, that is, nuclear proteins with putative DNA-binding functions AFF1 (AF4), MLLT3 (AF9), MLLT10 (AF10), MLLT1 (ENL), and OCEL1 (ELL); histone acetyltransferases CREB binding protein (CBP) and EP300 (P300) (226,229); FOXO (AFX) and MLLT4 (AF6) with the coil–coil oligomerization domains, and the Septin family genes SEPT2, SEPT5, SEPT6, SEPT9, and SEPT11 that interact with cytoskeletal filaments during the mitosis. The unifying features of many of the partner genes are their function in regulation of the rate of transcriptional elongation (211). Some, such as ELL, are involved directly in regulating and reducing “pausing” of the transcription complex; others, such as ENL and its homologous protein, AF9, recruit many factors required for the *MLL* complex including other partner proteins, such as AF4 and AF10. *MLL* expression appears to be closely regulated by a number of miRNAs, including miR17-92 (46) and miR196b (45).

The clustering of the breaks makes it possible to use a single cDNA probe spanning the breakpoint and a single restriction enzyme digest to detect the rearrangement in virtually any patient on Southern blot analysis. For the common breakpoints in which the other partner chromosome has been cloned, one can also use RT-PCR (230). In fact, multiplex PCR has been developed to screen for the common translocations simultaneously (231). Partial tandem duplication (PTD) within the *MLL* gene has been described as a novel genetic alteration in 90% of AML with trisomy 11 and in 11% of patients with AML and normal karyotype, and it was shown that this rearrangement is associated with a poor prognosis (232,233). PTD within *MLL* are found in blood and bone marrow from normal individuals as well (234,235). However, whether the origin and the composition of PTD within *MLL* in these individuals are the same as in AML patients or are distinct remains a matter of controversy.

Regardless of myeloid or lymphoid lineage involvement, leukemia patients with 11q23/*MLL* rearrangements have a very dismal prognosis, particularly infant ALL patients with the t(4;11) (8,23,24,236–238). However, patients with t(9;11)(p22;q23) tend to have an intermediate response to standard therapy (8). In the 2008 WHO classification of hematopoietic and lymphoid tissues, the t(9;11) is listed as one of the subcategories of AML with recurring genetic abnormalities (Table 75-1) (4). Patients with the t(9;11)(p22;q23) had rates of complete remission and 10-year survival of 84 and 39%, respectively (8,22). In children AML with 11q23/*MLL*

rearrangement, t(6;11), t(10;11), and t(11;19) are associated with a very poor prognosis, whereas patients with t(1;11) and t(9;11) display a better outcome (8,22,236).

### 75.7.5 Inv(3)(q21q26.2)/t(3;3)(q21;q26.2) with Thrombocytosis and Over-Expression of EVI1

The t(3;3) and inv(3) are one of the rare recurring chromosome abnormalities, occurring in only 1% of AML cases (8,239). It is detected in de novo AML, in CML in blast crisis, and in therapy-related MDS/AML (Table 75-1). Abnormalities involving 3q26.2 in AML are associated with thrombocytosis in the peripheral blood and increased atypical megakaryocytes in the bone marrow (132,239).

The inv(3)/t(3;3) results in the activation of the *EVI1* gene. Activation of *EVI1* in hematopoietic cells can occur by juxtaposition of the gene to enhancer elements of the ribophorin (*RPN1*) gene located at 3q21 in inv(3) and t(3;3) (240). The genomic breakpoints in *EVI1* are either 5' of the gene in the t(3;3) or 3' of the gene in the inv(3) (241). *EVI1* is a zinc-finger transcription factor that contains a seven-zinc-finger domain at the N-terminal end, a three-finger domain in the central part of the molecule, and an acidic domain distal to the second group of zinc fingers (153). Depending on its binding partners, *EVI1* can act as a transcriptional activator to promote the proliferation of HSCs through binding to GATA2 or as a transcriptional repressor inhibiting erythroid differentiation when it binds to GATA1. Abnormal over-expression of *EVI1* can be detected in patients with myeloid leukemia and a normal karyotype, suggesting that inappropriate activation of this gene occurs through various mechanisms (133,242). All patients with inv(3q) or t(3;3) are associated with a poor prognosis. As the most common additional aberration to inv(3q)/t(3;3), loss of chromosome 7 contributes to the adverse prognostic impact on relapse-free survival and overall survival (8).

### 75.7.6 t(6;9)(p22;q34) and the DEK/NUP214 Fusion

t(6;9)(p22;q34) is detectable in less than 1% of newly diagnosed AML and is characterized by increased basophilia, single or multi-lineage dysplasia in adult patients, variable FAB morphology, and a high incidence (70%) of FMS-like tyrosine kinase 3 (*FLT3*) gene internal tandem duplications (ITD) (4,8,22,243). The translocation results in the juxtaposition of *DEK* on chromosome 6 with *NUP214* (also known as *CAN*) on chromosome 9. *NUP214* is an essential component of the nuclear pore complex at the nuclear envelope and is required for proper nucleocytoplasmic transport. The *DEK* protein is a major component of the chromatin to modify the DNA structure by introducing supercoils. This results in the creation of a nucleoporin fusion protein that acts

as a transcription factor and also alters nuclear transport. Notably, the *NUP214* gene is fused to *ABL1* in episomal amplification in T-cell ALL (see below in T-ALL). Patients with the t(6;9)(p23;q34) have a poor outcome with standard therapy. In a recent analysis of 5876 younger adults with newly diagnosed AML, the complete remission rate and 10-year survival were 88 and 27%, respectively in the patients with t(6;9) (8). The poor prognosis is likely also due to the high incidence of *FLT3*-ITD mutations (243).

### 75.7.7 t(1;22)(p13;q13) and the RBM15-MKL1 Fusion

t(1;22) is a very rare entity (<0.5%) exclusively in newly diagnosed AML (8,244). It typically presents with megakaryoblastosis occurring in infants, and is associated with AML-M7 in young children, most often without Down syndrome and prior MDS or transient myeloproliferation (245). This translocation involves the RNA-binding motif protein-15 (*RBM15*, also called *OTT*) at 1p13 and a DNA-binding motif protein known as megakaryocyte leukemia-1 *MKL1* (also known as *MAL1*) at 22q13. *RBM15* belongs to the *SPEN* (Split-end) family of proteins that function as repressors in various signaling pathways and may bind to RNA through interaction with spliceosome components (246). *MKL1* is involved in the normal production of platelets (247). The *RBM15-MKL1* fusion protein shares many features with the *MLL* fusion in infant leukemia, and is assumed to participate in the modulation of chromatin organization through the binding of AT-rich DNA sequences, recognized by the AT hook motif in *MLL* fusions and by the scaffold attachment factor box in the *OTT-MAL* fusion, in *HOX*-induced differentiation, or extracellular signaling pathways (248). The prognostic significance of t(1;22) in AML treated with modern therapy is not clear (244).

### 75.7.8 Mutations of NPM1, FLT3, and CEBPA in AML with Normal Karyotypes

As noted earlier, recurring chromosome translocations, inversions, and chromosomal gains and losses are detectable in 50–80% of de novo AML and up to 92% of t-AML/MDS. The remaining patients with AML will have a normal karyotype by conventional cytogenetic analysis. This is a very heterogeneous group of patients with variable age, morphological features, and clinical course. In general, AML patients with a normal karyotype have an intermediate prognosis (8,177).

Using genomic microarray analysis, and other molecular techniques, many novel gene mutations have been identified in AML with normal karyotypes (NK-AML) and are associated with various prognoses. Identification of these mutations provides new insights into the pathogenesis of this group of NK-AML, and it also may

provide novel therapeutic targets (164). PTD of *MLL* is detected in 5–11% of NK-AML and up to 90% of AML with trisomy 11, and is associated with reduced remission duration (249). DNA methyl transferase and/or HDAC inhibitors may have some promise in NK-AML with *MLL* PTD. ITD and tyrosine kinase domain (TKD) mutations of *FLT3* occur frequently in AML with t(6;9) and in APL with t(15;17), and are particularly common in NK-AML (25–34%); they are associated with reduced remission duration and survival in adult NK-AML, especially in the absence of the wild-type allele (164). *FLT3* is a member of the class III receptor tyrosine kinase family, and plays an important role in proliferation, survival, and differentiation of hematopoietic progenitor cells. Brain and acute leukemia, cytoplasmic (*BAALC*), located at 8q22.3, encodes for a cytoplasmic protein with yet unknown function, and its high-expression adversely impacts outcome in adult NK-AML. In contrast, mutations in CCAAT/enhancer binding and protein alpha gene (*CEBPA*) are detected in about 15–18% of NK-AML, and are associated with improved remission duration and survival (164). More recently, patients with *CEBPA* double mutations including both frameshift mutations in the N-terminal and in-frame insertions or deletions in C- and N-terminals, frequently occurring on different alleles, have defined a distinctive disease entity with a very favorable prognosis. *NPM1* encodes for nuclear-cytoplasmic shuttling phosphoprotein with pleiotropic functions. *NPM1* mutations are detected in 25–35% of AML, and in 45–64% of NK-AML, and are associated with good prognosis, in particular in the absence of *FLT3*-ITD (250). AML with *NPM1* mutations show a distinct gene expression profile that is characterized by up-regulation of *HOX* genes (251). In addition, mutations of *ERG*, *EVII*, *MN1*, and *WT1* are associated with a poor prognosis in AML (4). Both AMLs with *NPM1* and *CEBPA* mutations are included as a provisional disease entity in the 2008 WHO classification, and detection of *NPM1*, *CEBPA*, and *FLT3* mutations has entered clinical practice and affects diagnosis, risk assessment, and guidance of therapy (164).

## 75.8 AML AND MDS ASSOCIATED WITH PRIOR CYTOTOXIC TREATMENT

A distinctive disorder of bone marrow morphology and function that terminates in MDS or in AML has been recognized as a late complication of cytotoxic therapy used in the treatment of both malignant and non-malignant diseases (252,253). Characteristic non-random chromosome abnormalities are commonly observed in the bone marrow cells of patients with t-MDS/t-AML. These abnormalities differ in their type and frequency from those noted in AML developing *de novo*. In general, two distinct subtypes exist based on their prior treatment for primary cancer or disease, clinical presentation, and chromosome abnormal patterns, although the 2008 WHO

classification of myeloid neoplasms and acute leukemia no longer includes subcategories of these diseases based on previous treatment types (4). In patients with previous treatment with alkylating agents and/or irradiation, both of which are mutagenic, the disease occurs with latency of 4–6 years after the treatment for primary disease, and presents with an insidious MDS phase prior to t-AML. Abnormalities of chromosomes 5 and/or 7 are most common occurring in almost 70% of t-MDS/t-AML patients. Analysis of the data from patients with a deletion of the long arm of chromosome 5 has identified a critically deleted region at 5q31 that was consistently observed in every patient (98,107). Genes for a number of growth factors or growth factor receptors have been mapped to this band. A number of candidate tumor suppressor genes have been screened, but at present none has been shown to play a role in leukemogenesis (see Section 75.6.1) (110).

The other subgroup of t-AML/MDS, cancer patients have been treated with drugs that inhibit the ligase function of topoisomerase II (epipodophyllotoxins, anthracyclines, etc.), resulting in DNA with double-strand breaks. The leukemias that develop as acute disease with no previous MDS stage in these patients have a different karyotypic pattern, namely translocations involving the *MLL* gene at 11q23 and the *AML1* gene at 21q22 (94,252,254–258). Virtually all patients with t(11;16) (q23;p13) that involves the *MLL* and *CREBBP* genes have treatment-related hematologic disorders induced by exposure to topoisomerase II inhibitors (210,259). The genomic breakpoints in t-AML often coincide with topo II cleavage sites, DNase I-hypersensitive (HS) sites, and scaffold attachment regions, implying that these chromatin structural elements may influence the location of these translocation breakpoints (215–217,260–262). Therapy-related APL with t(15;17)(q22;q21) is particularly associated with exposure to mitoxantrone and epirubicin; both preferentially induce topoII-mediated DNA damage in a “hotspot region” within the *PML* gene. Whether DNA cleavage at this site can be the initiating event for all *PML* translocations is unclear, but some treatment-related leukemia cases had breakpoints within a few hundred nucleotides of the cleavage site (218,263,264). DNA topoisomerase II inhibitors can be found in some fruits and vegetables, soybeans, tea, cocoa, wine, pesticides, and specific derivatives of benzene (260). In fact, some bioflavonoids (quercetin, ellagic acid, genistein), which are advocated for adult consumption because of their supposedly cancer preventive properties, are potent topoisomerase II inhibitors. Nearly 80% of infants diagnosed with leukemia show an abnormality involving the *MLL* gene; it cannot be excluded that exposure of pregnant women to substances that are identified as topoisomerase II inhibitors might be critical in the development of acute leukemia in infancy (265). In fact, Greaves’ group performed genomic cloning of the t(4;11) in three children with ALL (266) They were able to obtain genomic DNA from the Guthrie filters of

newborn blood from these children. Using the appropriate genomic probes for the leukemic junction, they could show that the t(4;11) was present in all children at birth, indicating that leukemia developed in utero (267).

## 75.9 B-CELL ACUTE LYMPHOBLASTIC LEUKEMIA

Although the correlation of cytogenetic changes with morphology in AML led to the identification of the specific associations described above, this correlation was not useful in B-cell ALL, except for the t(8;14) and its variants in L3, B-cell ALL. However, with the widespread use of precise immunophenotyping, the correlation of certain chromosome rearrangements with specific immunologic subsets of ALL has been established (4).

ALL is the most frequent leukemia in children, with 85% being of the B lineage. A better understanding of the complex interrelation of the disease and patient characteristics with therapeutic intervention changed the prognosis in children with ALL. Long-term event-free survival, which is virtually synonymous with cure, which before 1965 was only 5%, now exceeds 80% (23,268,269). This is not the case in adult patients, where cure rates are only 20–40%. These striking differences in treatment response, as well as the new information regarding the clinical outcome of different genetic abnormalities in patients, support the theory that childhood and adult ALL represent two different subsets of the disease. For many years, metaphase chromosomes from ALL patients had poor morphology with indistinct bands, making an accurate analysis difficult. Thus, there were fewer reports of chromosome patterns in ALL than in AML. It was rigorously demonstrated for the first time at the Third International Workshop on Chromosomes in Leukemia (1981) that the karyotype is an important independent prognostic factor in ALL; this was confirmed in children by two major studies conducted in 1997 (61,269,270). The most useful prognostic indicators in ALL are age, white blood cell (WBC) count, immunophenotype, MRD detection, and karyotype (25,271–274). The incidence of chromosome abnormalities are sharply different in childhood and adult ALL, that is t(4;11) is most common in infant younger than 12 months, and t(12;21) and hyperdiploid karyotypes are common in pediatric ALL, and they are rare in adult ALL, whereas t(9;22) is frequently observed in adult patients and is uncommon in the childhood patients (275–278). In general, a hyperdiploid clone, t(12;21), and t(1;19) are associated with a favorable prognosis, and t(9;22) and some gene mutations and deletions, that is *CRLF2* and *PAX5*, are predictable for a poor prognosis (33,36,101,237,277,279–284).

### 75.9.1 t(9;22)(q34;q11.2)

The Ph chromosome is the most frequent rearrangement in 25% of adult ALL. However, it occurs in only

2–5% of childhood ALL (23,283). At the cytogenetic level, the breakpoints appear identical to those in CML; molecular analysis indicates that the breakpoint in the *BCR* gene on chromosome 22 is more proximal in about 50% of adult and 80% of childhood patients with Ph+ ALL. We also successfully used FISH in combination with morphological observation for distinguishing Ph-positive ALL from the lymphoid blast phase of CML on the basis of lineage involvements of cells: patients with CML had a multilineage disease, and in ALL it was lymphoblast restricted (64). There are two distinct molecular subgroups of ALL with t(9;22). In approximately 30–50% of adult patients, the molecular rearrangement is identical to that observed in CML, that is the t(9;22) produces a chimeric gene that encodes for a 210-kd fusion protein, and the Ph chromosome is present in both myeloid and lymphoid cells, suggesting that they actually are cases of CML in lymphoid blast crisis. In the remaining patients, the breakpoint in the *BCR* gene occurs in the m-bcr, and results in smaller fusion proteins (185–190 kd) (285–287). The Ph chromosome is restricted to myeloid cells, and disappear in hematologic remission, indicative of the origin of the Ph translocation in a more restricted, perhaps a committed B-lymphoid, progenitor (288). Both the 210- and 185–190-kd fusion proteins participate in constitutive signaling via the RAS pathway of signal transduction. Transgenic mice transplanted with p185 *BCR/ABL1* develop tumors more rapidly than those transplanted with p210 *BCR/ABL1* (287,289,290).

Children with Ph-positive ALL respond poorly to available therapy at diagnosis or in relapse (291). One exception is a subset of children with Ph-positive ALL and low leukocyte counts at presentation or good initial responses to prednisone therapy who appear curable with intensive chemotherapy alone (25,283). A similarly poor prognosis was reported in adults where, despite high remission rates comparable to those of Ph-negative ALL, remission duration and survival times were short (284). In the MRC/ECOG clinical trial, the 5-year event-free and overall survival rates in Ph-positive ALL patients were 16% and 22%, respectively, in comparison with 36% and 41% in those without the t(9;22) (101). The use of tyrosine kinase (TK) inhibitors, for example, Imatinib, has revolutionized the treatment of CML with a superior outcome of 97% complete hematological remission and 87% of complete cytogenetic remission in a 5-year follow-up study (20). Imatinib, and the second generation TK inhibitors, such as dasatinib and nilotinib, have been used as the front-line treatment options in Ph-positive ALL, in combination with chemotherapy, and have showed a significant improvement in complete remission (95%) and overall survival (over 50% with 3-years follow-up), although an improved treatment regimen is needed to overcome the frequent resistance to Imatinib and to improve the remission durability (292).

### 75.9.2 t(12;21)(p13;q22)

Molecular analysis has proved indispensable for identifying certain prognostic and therapeutically important genetic subtypes of ALL, for example, cases defined by the *TEL/AML1* (*ETV6/RUNX1*) fusion gene owing to the cryptic translocation t(12;21)(p13;q22) (293–298). The t(12;21) is present in about 25% of childhood ALL (274). However, because of the marked similarity of chromosomal segments involved in this rearrangement, it is essentially undetectable by conventional cytogenetic analysis. Only FISH or PCR techniques can reliably detect it (294,299–301).

The t(12;21) results in fusion of the 5' HLH domain of *ETV6* with the 3' DNA-binding and transactivation domain of *AML1/RUNX1* (295). The *ETV6* protein contains a helix–loop–helix (HLH) protein dimerization domain and an ETS DNA binding domain, and it functions as a transcriptional repressor (280,302). The *RUNX1* protein (*AML1/CBFA2*) is a member of a family of transcription factors with homology to the pair-rule *Drosophila* gene, *runt*. *RUNX1* heterodimerizes with *CBFB* (also known as *PEBP2 beta*) and form a transcription factor *CBF* [see AML with t(8;21) and inv(16)/t(16;16)]. The *ETV6/RUNX1* inhibits transactivation of gene expression by the normal *RUNX1* protein, which requires the HLH domain of *ETV6* (303,304). In more than a half of ALL patients with the t(12;21), the *ETV6* allele on the other chromosome 12 homolog is also deleted, indicative of a tumor suppressor effect of *ETV6* (304).

The *TEL/AML1* fusion sequences were found at birth in six of nine patients with childhood ALL (2–5 years of age) (305). These findings indicate that not only translocations had occurred in utero, but also cells with the translocation had proliferated at birth to be detectable with RT-PCR. As noted for other translocations, a number of years passed before the development of a fully malignant phenotype. Analysis of *TEL/AML* genomic sequences suggests that these events arise from error-prone non-homologous end-joining repair of double-strand breaks in DNA (306–308).

Patients with ALL and the t(12;21) generally have a favorable prognosis. Patients with the *ETV6* rearrangement had a much higher 5-year event-free survival than those without the rearrangement. In the MRC/ECOG study, the event-free and overall survival rates at 5 years of 368 childhood ALL patients with the t(12;21) were 89% and 96%, respectively (101,294).

### 75.9.3 t(4;11)(q21;q23)

The most common translocation involving chromosome band 11q23 is t(4;11)(q21;q23). It is observed in more than 60% of infants, 2% of children, and 3–6% of adults with ALL (309). The association of t(4;11) with neonatal or early-childhood ALL is particularly interesting in

view of the low incidence of ALL in this age group; acute leukemias in this age group are usually of the myeloid type and, as noted earlier, usually involve the *MLL* gene at 11q23 (200,214). Children with a t(4;11) have very high leukocyte counts (median WBC 214000/mm<sup>3</sup>), which is a poor prognostic factor (25,310). Although the morphology of some cells often appears lymphoid, other features are more suggestive of a monocytic leukemia. Thus, these cells appear to be very early precursor cells that have dual lineage capabilities. The t(4;11) results in a fusion between *MLL* on 11q23 with *AF4* at 4q21 (203,207). This translocation can be detected by RT-PCR in virtually all t(4;11) patients (238). Using molecular FISH probes for *MLL* to screen cells from infant leukemias, 73–80% were found to have *MLL* rearrangements including t(4;11), t(11;19), and t(9;11) (311). In a clinical trial of the Children Oncology Group, the 5-year event-free survival for infant patients with these three *MLL* translocations was significantly lower than that of infants lacking an *MLL* rearrangement or other *MLL* rearrangements: 22–30% vs. 53–61% (24,238). Because of the dismal clinical outcome for both adults and children with t(4;11), intensive therapy and/or allogeneic HSC transplantation might be beneficial.

### 75.9.4 t(1;19)(q23;p13.3)

Another recurring chromosome abnormality is t(1;19)(q23;p13.3), which has been identified in about 5–6% of all childhood ALL and in 30% of childhood ALL with pre-B cell phenotype (312,313). The t(1;19) occurs either as a reciprocal translocation, t(1;19)(q23;p13.3) or, more often, as an unbalanced form, that is, der(19)t(1;19)(q23;p13.3) (314). There is no difference in clinical and laboratory features and event-free survival for these two subtypes. This breakpoint has been cloned and fused the *PBX* gene on chromosome 1 and the *TCF3* (*E2A*) gene on chromosome 19 at 19p13.3 (312,315,316).

The *TCF3* gene encodes for two transcription factors (E12 and E47), which bind to enhancer elements in the *IGK* gene and to the regulatory elements of other genes. *PBX1* at 1q23 is a homeobox (*HOX*) gene that encodes for DNA-binding transcription factors and regulates developmental processes and hematopoiesis (313). *TCF3/PBX1* fusion mRNAs contain the transcriptional activating domain of E12/E47 and the DNA-binding and protein dimerization domains of *PBX1*. The fusion protein may lead to the transactivation of a number of genes that are not normally expressed in lymphoid tissues, such as over-expression of WNT-16 transcripts (63,317,318).

t(1;19) was associated early treatment failure and poor prognosis. However, recent studies have showed that this adverse prognosis can be overcome by more intensive chemotherapy. In the MRC/ECOG study, the event-free and overall survival rates at 5-years were 80% and 84%, respectively, very comparable to those (84% and 93%) with a hyperdiploid karyotype (101). In fact,

t(1;19), t(12;21) and hyperdiploidy are all associated with a favorable prognosis (25).

### 75.9.5 Hyperdiploid Karyotype

The leukemic cells of some patients with ALL are characterized by a gain of many chromosomes and fewer structural abnormalities. Chromosome numbers usually range from 50 to 60, and a few patients have up to 65 chromosomes. Although identical karyotypes are unusual, certain additional chromosomes are commonly seen. Gain of chromosome 21 is the most common aberration, following by +4, +6, +10, +14, +17, and +18. It is interesting that some of these chromosomes, particularly chromosomes 10, 18, and 21, are also seen as additional in patients with near haploidy, with chromosome numbers of 26–36 (median 28) (319). Structural abnormalities, such as duplication of the long arm of chromosome 1, iso-chromosome of 17q, as well as t(9;22) and t(1;19) may occur in a hyperdiploid clone (up to 25%). In general, patients with a hyperdiploid clone have a very favorable overall survival, which is often coincident with clinical features of a good prognosis, including age between 1 and 9 years, low WBC count, and favorable immunophenotypes (non-T or B markers), that is early pre-B or pre-B. Gain of chromosomes 4 and 10 appears to be the most influent chromosome aberrations that predict a good prognosis, whereas other structural aberrations did not appear to affect event-free survival except for a poor outcome associated with t(9;22) and iso-chromosome 17q (23).

### 75.9.6 Hypodiploid Karyotype

A hypodiploid clone with fewer than 46 chromosomes can be detected in about 5–6% of ALL patients. There are three distinct subgroups of hypodiploidy in ALL, that is near-haploidy (23–29 chromosomes), low hypodiploidy (33–39 chromosomes), and high hypodiploidy (42–45 chromosomes) (320). The near-haploid clone is often accompanied by a doubling of the chromosome complement resulting in a hyperdiploid population with a gain of two copies of certain chromosomes, which is distinguishable from the more common hyperdiploid clone with a single gain of certain chromosomes. In some patients, cytogenetic analysis may detect the doubling clone only. ALL patients with hypodiploid clones generally have a poor prognosis, especially patients with near-haploid and low-hypodiploid clones (320). In this regard, it is critical to avoid confusing the doubled (tetraploid) populations of a hypodiploid clone with a true hyperdiploid population, as the prognosis is sharply different between these groups.

### 75.9.7 9p Abnormalities in ALL

Deletions of 9p occur in about 5–10% of childhood and adult ALL patients as a single abnormality or as a part

of a complex clone with other numerical and structural abnormalities. Del(9p) can be present in various forms on cytogenetic analysis, such as del(9p), add(9p), der(9)t(v;9)(v;p), or a dicentric chromosome with 9q (23).

Application of genomic microarray analysis has identified alternations in genomic imbalances, and genes that regulate B-lymphoid development in over 60% of B-ALL (34). A mono-allelic deletion of the *PAX5* gene at 9p13.2 was detected in 28% of ALL patients with a cryptic or a large deletion involving 9p (321). Deletion or mutation of the *PAX5* gene results in reduced level of the *PAX5* protein or the generation of hypomorphic alleles, thereby leading primarily to loss of function. A somatically acquired mutation in the Janus kinase (*JAK2*) gene on chromosome 9p24 has been reported in 18% of patients with Down syndrome associated ALL, but is not commonly found in ALL patients without Down syndrome or in patients with Down syndrome associated acute megakaryoblastic leukemia (33,322,323). Notably, this *JAK2* mutation (R683) is not the same mutation as that seen in MPN, that is the V617 mutation. Deletion of 9p is an unfavorable risk factor associated with a high rate of relapse for pre-B-ALL in children and similar to those with poor prognosis t(9;22)/BCR-ABL positive ALL (324,325).

### 75.9.8 Over-Expression of the *CRLF2* Gene at Xp22.3/Yp11.3 in B-ALL

Using FISH and genomic SNP array techniques, the *CRLF2* (cytokine receptor-like factor 2) gene at the tip of the short arm of the sex chromosomes, that is Xp22.3 and Yp11.3, was found to be deregulated in up to 7% of all pediatric B-ALL and in more than 60% of Down syndrome-associated B-ALL (33). *CRFL2* rearrangements seem to be mutually exclusive with the common chromosome aberrations in ALL. Deregulation of the *CRLF2* gene in ALL results from different mechanisms. A cryptic chromosome translocation of t(X;14) or t(Y;14) results in over-expression of the *CRLF2* due to the juxtaposition of the enhancer of the *IgH* gene to the *CRLF2* gene (326). An interstitial deletion involving the *P2RY8* gene of the PAR1 (pseudoautosomal region 1) at Xp22.3/Yp11.3 leads to the juxtaposition of the promoter of the *P2RY8* gene to the *CRLF2* gene (33,327). An activating point mutation (F232C) of the *CRLF2* has been identified in some patients with B-ALL (328).

Deregulation of the *CRFL2* gene in B-ALL is associated with the *JAK2* mutations (276,287). In ALL, *JAK* mutations including *JAK2* R683G are common (11%), and over 50% of B-ALL patients with *CRLF2* rearrangements have *JAK* mutations. In Down syndrome-associated ALL, nearly all patients with *JAK2* mutation have *CRLF2* over-expression. In vitro assays determined that *CRLF2* over-expression or *JAK2* mutation alone will not confer cytokine-independent growth to hematopoietic progenitor cells. However, transduction of both

mutations together will result in the transformation of Ba/F3-EpoR cells to cytokine-independent growth (33). The JAK/STAT5 phosphorylation is induced as a consequence of the *CRLF2* rearrangements and *JAK2* mutations in ALL. The transformation can be abrogated by pharmacologic JAK inhibitors (33,34).

Over-expression of the *CRLF2* gene is associated with an extremely poor treatment outcome with a high rate of relapse in pediatric B-ALL (327,329,330). Thus, the *CRLF2* rearrangements and *JAK2* mutations in ALL provide novel diagnostic, risk stratification, and therapeutic opportunities in ALL.

## 75.10 RECURRING CHROMOSOME AND GENOMIC ABNORMALITIES IN T-CELL ALL

Compared with the high frequency (80–90%) of chromosome abnormalities in B-cell ALL, an abnormal karyotype is present in about 50–70% of patients with T-ALL (274,331). Recently, gene expression profiling and genomic SNP microarray studies have identified various novel genomic alterations and defined several distinct genetic subgroups of T-ALL that correspond to T-cell development (332,333). The most common recurrent cytogenetic abnormalities occur in various translocations with the alpha/delta TCR loci (*TRA/TRD*) at 14q11.2, the beta locus (*TRB*) at 7q34, and the gamma locus (*TRG*) at 7p14 (Table 75-2). The common partner genes are *TAL1/SCL* (1p32), *HOX11L2/TLX3* (5q35), *HOXA* (7p15), *MYC* (8q24.1), *TAL2* (9q31), *HOX11/TLX1* (10q24), *RBTN1/LMO1* (11q15), *RBTN2/LMO2* (11p13), *CCND2* (12p13), *TCL1* (14q32), and *LYL1* (19p13) (Table 75-2) (201,334–339). With few exceptions, the involved gene on the partner chromosome encodes a cell cycle inhibitor or a transcription factor whose expression is deregulated or activated as a result of juxtaposition with the regulatory regions of one of these TCR loci. Some non-TCR loci translocations are also common in T-ALL, such as the *SIL-TAL1*, *PICALM-AF10*, *MLL-ENL*, *HOX11L2-BCL11B*, *ETV6-JAK2* fusion, and the *NUP214-ABL1* episomal amplification (339,340). Other abnormalities include genomic micro-deletions, such as deletion of the short arm of chromosome 9 at the *CDKN2A* tumor suppressor locus containing the *p16/INK4a* and *p14/ARF*, both control cell cycle progression and *P53* mediated apoptosis. Gene mutations, involving *NOTCH*, *JAK1*, and *FLT3*, are also found in T-cell ALL. The different chromosome and genomic abnormalities in T-ALL likely reflect different pathways and their cooperation in leukemogenesis in T-ALL (341). Notably, in many cases, these chromosome abnormalities are cryptic and can be detected only by molecular cytogenetic techniques, that is, FISH or PCR. SKY was used to perform a study on samples from 15 T-ALL patients (342). Although no recurring translocations were identified, the cytogenetic findings in some

patients were clarified. Only five patients had a normal karyotype.

The t(10;14)(q24;q11.2) and its variant t(7;10)(q34;q24) are detected in 5–10% of patients with T-ALL or T-cell lymphomas (343). The t(10;14) and t(7;10) result in the translocation of *TLX1*(*HOX11*) to *TRA/D* and *TRB*, respectively, leading to over-expression of *TLX1*. However, *TLX1* over-expression in leukemic blasts has also been observed in the absence of 10q24 rearrangement in up to 50% of T-ALL cases. Therefore,

**TABLE 75-2** Recurring Structural Rearrangements in Malignant Myeloid Diseases

Disease	Chromosome Abnormality	Involved Gene
Chronic myeloid leukemia	t(9;22)(q34;q11.2)	<i>ABL/BCR</i>

AML, acute myeloid leukemia; AMMoL, acute myelomonocytic leukemia; AMoL, acute monoblastic/monocytic leukemia; APL, acute promyeloid leukemia; CML, chronic myelogenous leukemia.

other mechanisms, such as disruption of gene silencing, may lead to aberrant expression of the gene as well. The gene expression pattern of *TLX1*-expressing lymphoblasts is similar to that of early cortical thymocytes. Thus, the lack of expression of anti-apoptotic genes during this stage of thymocyte development (and in *TLX1*-expressing lymphoblasts) may explain why pediatric and adult patients with this type of lymphoblast have a highly favorable outcome. Somatic inactivating mutations or deletions in the plant homeodomain finger 6 (*PHF6*) locus located on the X chromosome at Xq26.3 were detected in 16% of pediatric and 38% of adult primary T-cell ALL (344), which is exclusively in T-ALL samples from male patients. *PHF6* is an X-linked tumor suppressor in T-ALL and loss of *PHF6* is associated with aberrant expression of the *TLX1* (*HOX11*) and *TLX3* (*HOX11L2*) transcription factor oncogenes.

Another recurring rearrangement in T-cell neoplasia is the *inv*(14)(q11.2q32) or its variant *t*(14;14)(q11;q32), particularly in T-cell prolymphocytic leukemia (T-PLL) and phytohemagglutinin-stimulated lymphocytes from patients with AT, as well as in the leukemic cells of AT patients in whom this disease evolved (345). Japanese adult T-cell leukemia-lymphoma patients have a high incidence of 14q11 breaks. Thus, in some of these T-cell diseases breaks occur in either 14q11 or 14q32, or in both bands in the same patient; in B-cell disorders, however, breaks occur essentially only in 14q32, and they rarely involve 14q11 (346). One of the first translocations to be cloned in T-cell leukemia was the *t*(8;14)(q24;q11). The breakpoint involves *MYC* at 8q24, and the *TRA* gene. The break in *MYC* is 3' of the third exon and *MYC* remains on chromosome 8; in *TRA* the break is just 5' of a *Ja* segment (*JaD*) (347). This translocation is comparable to these involving the immunoglobulin light-chain genes in B-cell lymphomas in which *MYC* also remains on chromosome 8. *TRA* is also involved with translocations affecting 14q32 and the heavy chain gene in the *inv*(14) (345). Another translocation of special interest is the *t*(1;14)(p33;q11). The translocation juxtaposes the *TAL1* (*SCL*) gene at 1p33 with the *TRD*, and it occurs in about 3% of T-ALL patients (345). Probes for *TAL1* detect a 90-kb deletion involving the 5' region of the *TAL1* gene in 25% of patients (348). *TAL1* is never expressed in lymphoid cells and the translocation or deletion results in its inappropriate expression in these cells (349). Analysis of mRNA from T-ALL samples has revealed ectopic expression of *TAL1* in 35% of patients whose cells have neither a translocation nor a deletion. Thus, *TAL1* is expressed in over 60% of T-ALL patients, which makes it a very critical gene in this leukemia (349). Another common translocation involves either 11p13 or 11p15 and *TRA*; the genes on 11p are *LMO1* (formerly Rhombotin, *RBTN1*) at 11p15 and *LMO2* (*RBTN2*) at 11p13. Like the *TAL1* gene, *LMO1* and *LMO2* are not expressed in normal T-cells (336).

The extra-chromosomal episomal *NUP214-ABL1* amplification is a cryptic abnormality, and occurs in about 6% of T-ALL cases. The extra-chromosomal amplifications contained *ABL1*, *LAMC3*, and *NUP214* genes, localized within a 500-kb region on 9q34, and result in the *NUP214-ABL1* fusion genes. The copy number of the episome may vary from cell to cell, increasing due to unequal segregation during cell division. FISH analysis using probes for *ABL* is the only reliable means to reveal a variable spectrum of multiple uncountable copies of the *ABL* locus in interphase nuclei and metaphase cells. *ABL* FISH signals are not attached to any metaphase chromosomes or exceptionally intrachromosomal amplifications exist as small homogenous staining region. In many patients, the *NUP214-ABL1* amplification is a part of complex karyotypes, including some of the recurrent translocations seen in T-ALL. The 9q34 amplification often coexists with a 9p deletion involving *CDKN2A* and *CDKN2B* and ectopic expression of *TLX1* or *TLX3* (180). The *NUP214-ABL1* fusion is associated with aggressive disease and poor outcome in childhood T-ALL. Like *BCR-ABL1*, the *NUP214-ABL1* fusion is a constitutively active tyrosine kinase with transforming activity in vitro. However, because of the heterogeneity in the genetic lesions observed in many cases, the response to Imatinib in *NUP214-ABL1* positive T-ALL patients should be evaluated with caution. *ABL1* quantitative RT-PCR may be easily applied to monitor MRD.

### 75.10.1 *NOTCH1* Activating Mutations and Its Pathway in Leukemogenesis of T-ALL

About 5% of T-cell ALL patients have the translocation *t*(7;9)(q35;q34.3) between the *TCRB* at 7q35 and *NOTCH1* (*TAN1*) on chromosome 9 (350–352). In contrast to the translocations discussed above, rearrangements involving *NOTCH* disrupt the coding portion of the *NOTCH* gene, resulting in a truncated form of the *NOTCH* protein. This truncated form of protein produces T-cell malignancies when introduced into murine bone marrow (353). *NOTCH* family proteins are trans-membrane receptors, and *NOTCH1* signaling is required for commitment to the T-cell lineage and for the proliferation of T-cell progenitors in the thymus (354,355). Point mutations, insertions, and deletions of *NOTCH1* have been identified in more than 50% of all T-ALL (354,356), although the precise mechanisms by which *NOTCH1* causes T-cell ALL are not yet fully elucidated. Deletion of the *NOTCH1* promoter can also result in activation of the *NOTCH1* gene from cryptic initiation sites. Spontaneous deletion of the *NOTCH1* locus is seen in approximately 75% of *IKZF1*-deficient T-cell ALL cases (357). Patients with T-cell ALL demonstrating a *NOTCH1* mutation or a related mutation in *FBXW7* may represent a subset with superior event-free and overall survival rates when compared with other

patients with T-cell ALL (180,274,358,359). Functional analysis showed that gain-of-function mutations in *NOTCH* result in T-ALL in mice (352).

Both children and adults with T-cell ALL are generally treated with high-risk protocols and often have comparably favorable outcomes. In contrast to B-ALL, cytogenetic abnormalities in T-ALL are not strongly associated with a specific prognosis. In childhood T-ALL, the outcome is similar between patients with an abnormal karyotype and patients with a normal karyotype. However, T-cell ALL with low expression of both *ERG* and *BAALC* genes by RT-PCR is associated with significantly lower relapse rates compared with other T-cell ALL (17 vs. 60%) and higher 4-year overall survival (69 vs. 30%), and patients with *NOTCH* activating mutations have a rapid early response to treatment (274).

### 75.11 LEUKEMIA IN CHILDREN WITH DOWN SYNDROME

Children with Down syndrome have about a 20-fold increased risk of developing acute leukemia, 50% of which will be acute megakaryoblastic leukemia. About 10% of infants with Down syndrome develop transient myeloproliferative disease (TMD), a profound leukocytosis with blasts indistinguishable from leukemic megakaryoblasts. TMD usually disappears spontaneously during the first months of life. However, approximately 25% of those who present with TMD will develop acute megakaryoblastic leukemia in the first 4 years of life (360). Most Down syndrome children with AML have an abnormal karyotype, most commonly trisomy 8 (25%) or, less commonly, trisomies 19 or 21–13% and 17%, respectively (361). The role of the extra copy of chromosome 21 in the development of leukemia is unknown. A gain of chromosome 21 is the most common numerical change in both ALL and AML in children and has led to the hypothesis that over-expression of genes present on chromosome 21 may alter expression of genes on other chromosomes that subsequently affect hematopoiesis (270). In fact, increased levels of chromosome 21-encoded tumor invasion and metastasis factor (*TIAM1*) mRNA were reported in the bone marrow of children with Down syndrome during the acute phase of AML-M7 (362). Another hypothesis suggests that disomic homozygosity for a predisposing mutated allele of a putative suppressor gene on chromosome 21 may play a role in leukemogenesis. In support of this, in cases of TMD, maternal age was lower (about 27 years) compared with true leukemia (about 40 years) (361). Cavani et al. (1998) analyzed cytogenetic heteromorphisms and 26 polymorphic DNA markers from the long arm of chromosome 21 and showed an increased number of pericentromeric crossovers between the non-disjoined chromosomes in Down syndrome patients with AML-M7, compared to other Down syndrome cases (363). Recently, acquired mutations of *GATA1*, a transcription

factor that regulates growth and maturation of hematopoietic cells located on chromosome band Xp11, were detected in the majority of patients with Down syndrome-associated acute megakaryoblastic leukemia and almost all patients with TMD (191). Studying fetal tissue it was shown that *GATA1* mutations can occur prenatally and are likely early steps in leukemogenesis requiring additional genetic events and/or environmental exposures for the full development of leukemia (364). Whether *GATA1* mutation types and truncated protein expression level are associated with a risk of progression to acute leukemia in Down syndrome patients is controversial. The precise pathway by which *GATA1* contributes to leukemia in patients with Down syndrome remains under investigation.

### 75.12 PRENATAL ORIGINS OF CHILDHOOD LEUKEMIA

Recognition of the modest concordance of leukemia in monozygotic twins and analysis of DNA from blood spots on Guthrie cards from children who later developed leukemia indicate that the chromosome translocations resulting in abnormalities, such as *MLL* fusions, the *TEL/AML1* fusion in ALL, the *AML1/ETO* fusion in AML, and hyperdiploid clones in pediatric ALL, arise prenatally in utero at various frequencies (266,306). Using RT-PCR, Mori et al. detected *TEL/AML1* and *AML1/ETO* fusion transcripts in cord blood samples proposing that the abnormalities arise during fetal hematopoiesis (308). The frequency of detection of disease associated transcripts was approximately 100-fold greater than the incidence for development of leukemia, supporting the requirement of secondary, complementary mutations (308). As mentioned above, similar findings were identified when *GATA1* was studied in fetal tissue (364). Notably, pre-leukemia clones such as the *TEL/AML1* fusion occur in utero at a high rate in excess of clinical leukemia, and the concordance of infant ALL in monozygotic twins is not very high (around 10–20%) (307,365). Thus, all the data indicate that additional genetic mutations, most likely postnatal, are required for the development of an overt leukemia.

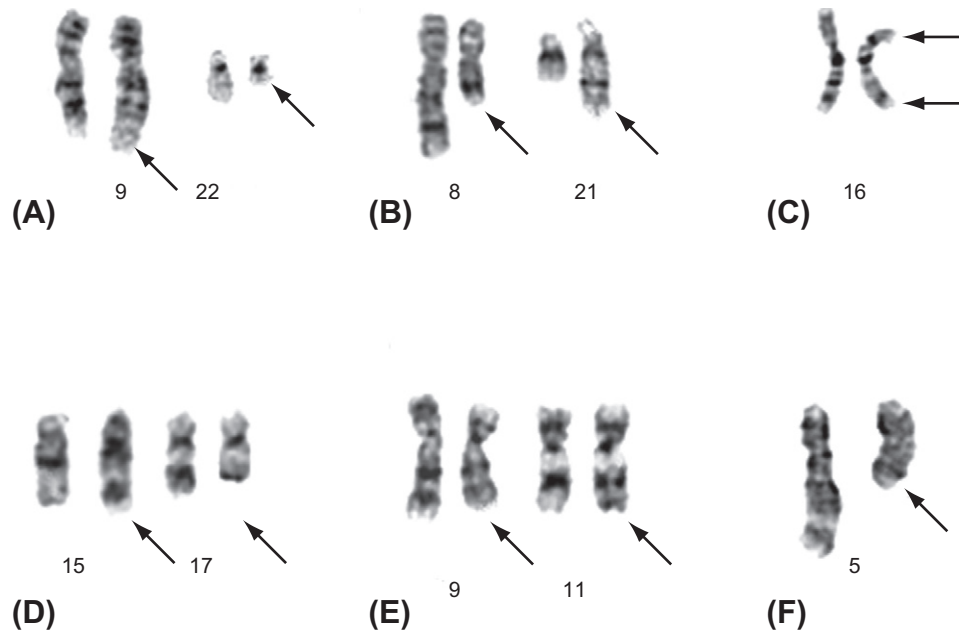

### 75.13 NON-HODGKIN LYMPHOMAS

The same explosion of information regarding the genes that are altered in the chromosome abnormalities described for the myeloid disorders has occurred in mature lymphoid disorders as well. There are some similarities, but also some major differences in the genetic (chromosome) changes that occur in these two lineages. In contrast to myeloid leukemia that are characterized with novel chimeric fusion genes and functions from chromosome translocations, lymphoid disorders are associated with over-expression of an intact oncogene, such as *MYC* or anti-apoptosis, that

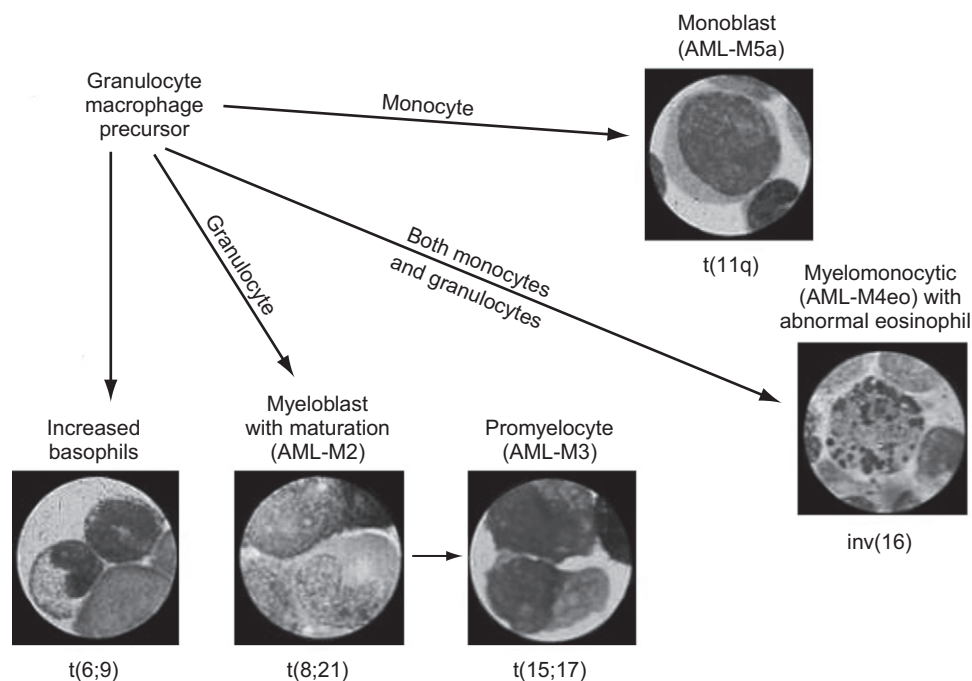

is, *BCL2*, due to this juxtaposition to the promoters and/or enhancers of immunoglobulin or T-cell receptor genes in various translocations. This section reviews the consistent translocations seen in mature B-cell NHL, and Burkitt lymphoma, and in some T-cell disorders (Figures 75-2–75-4).

### 75.13.1 t(8;14) and Its Variants, and the IGH-MYC Fusion in Burkitt and Other High Grade NHL

Some 80–90% of NHLs display chromosomal aberrations and, more importantly, many of the recurring

**FIGURE 75-2** Partial karyotypes from trypsin-Giemsa-banded metaphase cells depicting recurring chromosomal rearrangements observed in myelogenous leukemia. **A**, t(9;22)(q34;q11) in chronic myelogenous leukemia (CML). **B**, t(8;21)(q22;q22) in acute myeloblastic leukemia with maturation (AML-M2). **C**, inv(16)(p13q22) in acute myelomonocytic leukemia associated with marked eosinophilia (AMMoL-M4Eo). **D**, t(15;17)(q22;q11-12) in acute promyelocytic leukemia (APL). **E**, t(9;11)(p22;q23) in acute monoblastic leukemia (AMoL-M5). **F**, del(5)(q13q33) in therapy-associated AML (t-AML). The rearranged chromosomes are identified with arrows.

**FIGURE 75-3** Relationship of the subtypes of AML and the particular chromosome abnormality associated with each subtype. Each circle contains a photomicrograph illustrating the special features of the leukemic cells from the bone marrow of untreated patients; the particular chromosomal rearrangements associated with that type of leukemia are listed under the photomicrograph.

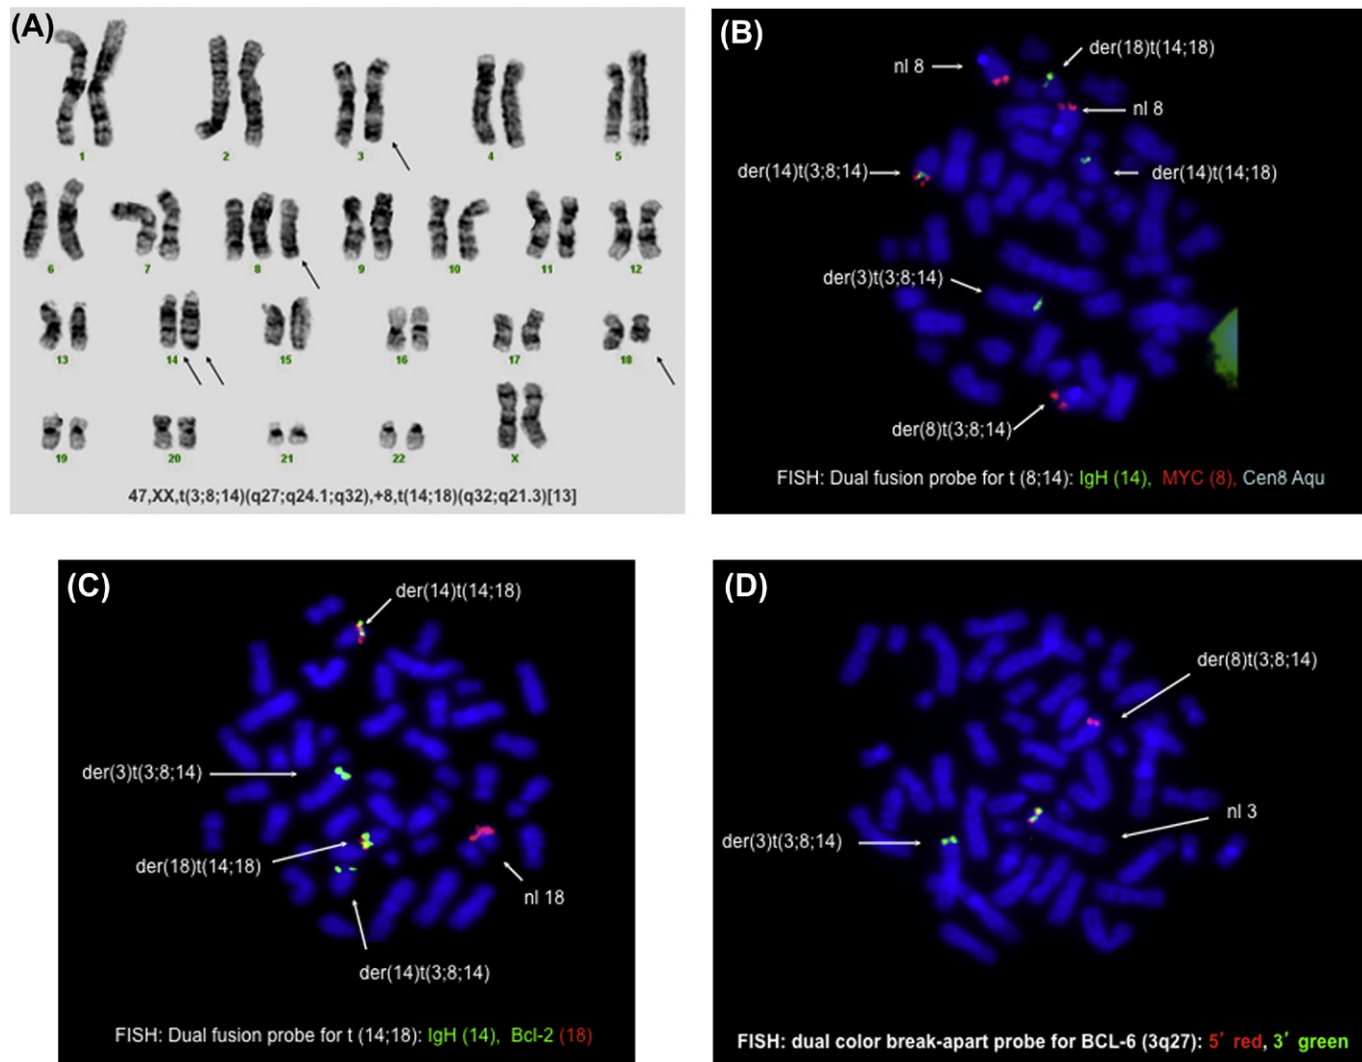

abnormalities correlate with histology and immunophenotype and may be independent prognostic factors (7). In 1972, Manolov and Manolova were the first to discover that cells of Burkitt lymphomas had an additional band at the end of the long arm of one chromosome 14 (14q+). In 1976, Zech and co-workers first observed that the end of one chromosome 8 was consistently absent, and they suggested that the missing part of chromosome 8 was translocated to 14, that is,  $t(8;14)(q24;q32)$  (Fig. 75.5a). The  $t(8;14)$  was also the first structural chromosomal abnormality in any hematological disease or carcinoma to be characterized at the molecular level (366,367). In fact, the  $t(8;14)$  and its variants are diagnostic for classic Burkitt leukemia and lymphoma, and is associated with a good prognosis in this entity when treated with intensive chemotherapies. It is found in both endemic African and sporadic Burkitt lymphoma, the latter being Epstein-Barr virus negative, and in immunodeficiency-associated Burkitt lymphoma. The  $t(8;14)$  is found in 75–85% of Burkitt lymphomas, and variant translocations,  $t(2;8)(p12;q24)$  and  $t(8;22)(q24;q11)$ ,

are described in 15–25% of cases (Table 75-2). All three translocations involved chromosome 8 with a break in the same band, 8q24. The reciprocal translocation fuses the protooncogene *MYC* (the cellular homolog of the avian myelocytomatosis virus) on chromosome 8 (band q24) to one of the immunoglobulin genes (heavy-chain, and K and L light-chain genes) which are located at the breakpoints on one of the three chromosomes, 14q32, 2p12, and 22q11, respectively (366). The 8q24 breakpoints demonstrate considerable variability at the molecular level, extending from over 300 kb centromeric to at least the same distance telomeric to *MYC* (368). Clustering of breakpoints has been described, and the location appears to differ in endemic, sporadic, and HIV-associated Burkitt lymphoma. Regardless of the molecular breakpoints, the consequence of these translocations is the deregulated expression of a full-length *MYC* protein, although the precise mechanisms by which deregulation occurs is unclear.

*MYC* acts as a transcription factor and plays a central role in a number of cellular processes, including

**FIGURE 75-4** The location of translocation breakpoints that involve *MLL* is indicated by colored bands. The involvement of *MLL* was determined by FISH, Southern blot analysis, or RT-PCR. Symbols to the right of the band indicate that the translocation has been cloned and the partner gene has been identified and named. (From Rowley JD [1999] *The role of chromosome translocations in leukemogenesis. Semin Hematol* 36[Suppl 7].)

**FIGURE 75-5** Cyto-genetic and FISH analysis reveal a complex karyotype with t(3;8;14) and t(14;18) in a lymph node specimen from a female patient with a high grade B cell lymphoma. A. Karyotype of a metaphase cell shows 47, XX,t(3;8;14)(q27;q24.1;q32),+8,t(14;18)(q32;q21.3). A three-way translocation among chromosomes 3, 8, and 14 involves the *BCL6* at 3q27, *MYC* at 8q24.1, and *IGH* at 14q32. These analyses indicate a so-called "double-hit lymphoma" with some overlapping features of Burkitt lymphoma and diffuse large B cell lymphoma, involving the *MYC*, *IGH*, *BCL2*, and *BCL6* genes. B. Using a triple-color FISH probe set for *MYC* (red), *IGH* (green), and chromosome 8 centromere (aqua), FISH analysis confirms the translocation between the *MYC* and *IGH* (fusion) with a red/green fusion on derivative chromosome 14, and the *IGH* split signal pattern due to the t(14;18), with a green signal on the derivative chromosome 18. FISH also confirm the presence of a third normal chromosome 8. C. FISH analysis using a *IGH/BCL2* dual fusion probe set displays the dual fusions of the *IGH* and *BCL2* genes resulting from the t(14;18), and confirms *IGH* involvement in t(3;8;14) with a split green signal on the derivative chromosome 3. D. Using a dual color break-apart probe set for the *BCL6* gene, FISH analysis confirms a split of the *BCL6* probe between derivative chromosomes 3 and 8. Thus, FISH using multiple probes confirms the involvement of *IGH*, *MYC*, *BCL2*, and *BCL6* in this sample.

proliferation and apoptosis (369). It is also a key component of the gene regulatory network in B cells, with DNA binding sites at the promoter regions as well as many non-coding regions. *MYC* participates in regulating chromatin dynamics by directly binding to several proteins that control epigenetic modifications of both histone and the DNA methylation state, and is also involved in the regulation of microRNA expression (370). Recently, gene expression profiling analyses have revealed a unique transcriptional and genomic profiling in Burkitt lymphoma with a high level of expression of *MYC* target genes, the expression of a subset of germinal-center B-cell genes, and the low-level of

expression of major-histocompatibility-complex class I genes and nuclear factor-kB target genes (371). Moreover, molecular classification of Burkitt lymphomas further confirmed an overall superior survival in patients with Burkitt lymphoma who had received intensive chemotherapy (372).

The t(8;14) and particularly other *MYC* abnormalities are also observed in other lymphoma, such as diffuse large B-cell lymphoma, DLBCL with overlapping features of Burkitt lymphoma, and follicular lymphoma, MCL, and T-cell leukemia/lymphoma and CLL (373,374). In all these diseases, *MYC* abnormalities are prognostic and associated with a more aggressive

phenotype, resistance to standard chemotherapy, and a higher mortality (375). So-called double-hit lymphomas often contain both *MYC* translocations and one or two other typical lymphoma-associated translocations, such as t(14;18)/*BCL2*, t(11;14)/*BCL1*, and t(3;14)/*BCL6* (Figure 75-5B–D) (376). In contrast to Burkitt lymphoma with a relatively simple karyotype of t(8;14) and its variants, these lymphomas often display a complex karyotype with multiple chromosomal abnormalities on cytogenetic analysis (377). Gene expression profiling analysis has further defined three subgroups of DLBCL, that is activated B-cell-like associated with poor prognosis, germinal B-cell-like with favorable prognosis, and others (378). The expression profile of a small group of DLBCL was similar to those of classic Burkitt lymphoma. Recently, next-generation sequencing analyses have identified that somatic mutations of the *MLL2* gene that encodes a histone methyltransferase occur in 32% of DLCL and 89% of follicular lymphoma. Moreover, 11–14% of DLCL and follicular lymphoma showed mutations in *MEF2B*, a calcium-regulated gene that cooperate with CREBBP and EP300 in acetylating histones (379,380).

Translocations involving chromosome band 3q27 are found in 8–12% of NHLs, in particular in high-grade lymphoma. Molecular characterization showed that the 3q27 breakpoints cluster in a 4-kb region of the gene called *BCL6* (*LAZ3*) (381). *BCL6* encodes a transcriptional regulator that is involved in germinal center formation and in the generation and maintenance of both T and B cells during immune responses. In many cases, *BCL6* occurs as a late and secondary genetic abnormality, in addition to t(14;18) or t(8;14), as discussed in those double-hit lymphoma. Similar to *MYC* in t(8;14) in Burkitt lymphoma, the translocation of 3q27/*BCL6* results in the deregulated expression of a full-length *BCL6* protein.

### 75.13.2 t(14;18)/IGH-BCL2 Fusion in Follicular Lymphoma and Diffuse Large B-Cell Lymphoma

Another common recurring translocation in NHL, t(14;18) (q32;q21), was first identified by Fukuhara and co-workers, in 1979, in poorly differentiated lymphocytic lymphoma (3). It has been detected in 80–90% of follicular lymphomas and in about 20% of diffuse B-cell lymphomas. The translocation results in the juxtaposition of the *BCL2* gene on chromosome 18 to the immunoglobulin locus, with consequent deregulated expression of an intact *BCL2* protein. The cloning of this gene led to the discovery of a new class of oncogenes, which, instead of promoting proliferation, contributed to the development of a neoplastic state by preventing programmed cell death. Breakpoints cluster in at least two sites in *BCL2*; the major cluster is in the 3' untranslated region (UTR) of the third exon.

The increased production of *BCL2* protein leads to prolongation of cell survival and the accumulation of follicular B cells (315,382). The *BCL2* rearrangement appears to occur in a very early multilineage progenitor stem cell (383). There are conflicting reports about the prognostic significance of having t(14;18), but several studies suggest that the level of *BCL2* expression and the site of *BCL2* breakpoint might be important (375). This translocation has been found in lymphoid hyperplasia and even in normal individuals (at low percentages and only by molecular and not standard cytogenetic techniques); it has therefore been postulated that it causes only proliferation and prolonged cell survival, and that additional genetic changes are required for neoplastic transformation (384). The long chronic phase (up to 10 years) before the inevitable terminal phase supports this hypothesis. It is important to understand that the detection of low-level *BCL2*-*IGH* rearrangement does not in itself necessarily reflect the presence of malignant cells in the sample, nor that the B-cell proliferation is a (transformed) follicular lymphoma.

### 75.13.3 t(11;14)/IgH-BCL1 Fusion in Mantle Cell Lymphoma

More recently, the importance of several other translocations has been recognized. One of these, the t(11;14) (q13;q32), has been shown to be associated with a relatively new pathologic entity known as mantle cell lymphoma (MCL), which was previously classified as low-to-intermediate-grade small cell lymphoma. Cloning of t(11;14) translocation breakpoints showed juxtaposition of the *IGH* gene (JH segment) to a putative oncogene, *BCL1*. The breakpoint was originally cloned by Tsujimoto and colleagues in 1984, who called the locus at 11q13, *BCL1*; no gene was identified initially, but several other groups analyzing other genes found that one of the cyclins (*CCND1*), also called *PRAD1* because it was isolated from a parathyroid adenoma breakpoint, was a partner in the translocation (385). Genomic 11q13 breakpoints are heterogeneous, extending over several hundred kilobases, but three clusters have been described. Besides MCL, the t(11;14) has also been reported in 3% of multiple myelomas (MMs) and up to 20% of PLL, but the breakpoint cluster in these diseases is located in the region containing the IgH constant segments, and thus appears to be distinct from that observed in MCL (386). *CCND1* is involved in cell cycle progression from the G1 to the S phase by forming a complex with CDK4 and activating the RB1-E2F1 pathway (see Section 75.13.6). It is likely that deregulated expression of the *BCL1* (*CCND1/PRAD1*) gene disrupts cell cycle control and cellular proliferation. Due to a large variation of breakpoints in *CCND1*, FISH using a cocktail of several overlapping BCA probes is by far the most sensitive method of t(11;14) detection in MCL. It was shown that FISH can detect t(11;14) in every patient with MCL, regardless

of their morphological or clinical presentation, whereas RT-PCR and conventional cytogenetics are successful in 50–60% and 70–75%, respectively (387). The detection of t(11;14)/IGH-CCND1 fusion is clinically significant because MCL has an aggressive clinical course and the morphology and immunophenotypes of MCL cells is variable, making it difficult to separate from CLL and other low-grade B-cell lymphoma and leukemia.

#### 75.13.4 Common Chromosome and Genomic Abnormalities in Chronic Lymphocytic Leukemia

CLL is the most common leukemia in the United States and Europe, accounting for about 30% of all leukemias. It is virtually unknown in people less than 30 years old, but after the age of 70 its incidence is about 50 cases per 100,000. It is considered to be a monoclonal neoplastic proliferation of small lymphocytes that in 95% of cases are of B-cell origin. There appears to be a genetic susceptibility to CLL because CLL is rare both in Asia and in Africa. The ethnic origin per se, however, does not influence the biology or clinical behavior of the disease. The ethnic variation appears to be maintained even after population migration to regions of high incidence; in the United States, CLL is much rarer in people from the Far East and in Japanese immigrants than in Caucasians. A recent intriguing finding is that in families in which both a child and a parent have CLL, the disease develops approximately 20 years earlier in the younger generation, a phenomenon called anticipation (388). This strongly supports the importance of genetic factors in the pathogenesis of CLL. The disease has a prolonged natural history, sometimes measured in decades; cells presumably gradually acquire sequential genetic abnormalities, rendering them more malignant.

The early studies of the cytogenetic pattern in CLL showed a normal karyotype in most samples, but it is now clear that the incidence of genetic abnormalities in CLL is critically dependent on the techniques used for their detection (27). Using immunostimulatory synthetic oligodeoxynucleotides containing unmethylated CpG motifs, such as DSP30 (CD40 ligand) as B-cell mitogen in combination with cytokine stimulation, that is interleukin 2 in cell culturing, abnormal karyotype can now be detected in more than 80% of CLL bone marrow or peripheral blood samples (389,390). Likewise, by using FISH screening of interphase cells, approximately 85% of CLL patients have a genetic abnormality (391). Current practice in the diagnosis of CLL now includes an interphase FISH analysis with a cocktail of probes for the following loci: p53(17p13), ATM(11q22.3), 13q14, chromosome 12 centromere, and IGH/14q32. In our experience, this increases the abnormal detection rate from approximately 25% (by cytogenetic analysis) to approximately 85%. Conventional and molecular cytogenetic methods have shown that the most common genetic abnormalities in CLL (up to 55% of all CLL

cases) are deletions or translocations of 13q14.3 (391). The presence of del(13q), detected by conventional chromosome analysis, as a sole abnormality is consistent with a good prognosis (median survival 133 months) (391). A detailed molecular analysis of this area, which is telomeric to the retinoblastoma gene *RB1*, has narrowed the interval to a minimally deleted region of no more than 10 kb, from which two candidate tumor suppressor genes, *LEU1* and *LEU2*, have been cloned (392,393). However, no mutations have been found in either gene in CLL (394). A third gene, *LEU5*, has homology to some zinc-finger proteins involved in cancer, but no alterations have been found in CLL (392). Recently, genomic microarray and gene expression profiling studies in CLL have defined two distinct subgroups of del(13q) in CLL based on the size of the deletion and the involvement of microRNAs (see Section 75.13.5) (395–397).

Trisomy 12, the most common abnormality detected by classic cytogenetic studies, is in fact only present in 16% of cases when using FISH. The gain of chromosome 12 as a sole abnormality or in the presence of del(13q) is associated with a good to moderate prognosis (median survival 114mos) (398). The mechanism by which trisomy 12 contributes to leukemogenesis in CLL is still unknown, although it cannot be excluded that amplification of one or more relevant genes may be responsible for the more malignant phenotype (391). About 7% of CLL patients have deletions of the *TP53* gene at 17p13.3, and these have been associated with poor survival (median survival 32mos) and drug resistance (391,399). Deletions of chromosome band 11q22 are noted in 18% of cases of CLL using FISH. This abnormality is associated with a moderate to poor outcome (median survival 79mos) (391). The *ATM* (ataxia–telangiectasia mutated) gene is located within the minimal region of loss of 11q22.3, and its inactivation may interfere with normal lymphoid function (400). Notably, both deletion of *P53* and *ATM* in CLL are often observed as secondary abnormalities during disease progression. Loss of material on the long arm of chromosome 6 at 6q23 has been found in 6% CLL patients, and it may contain an as-yet unidentified tumor suppressor gene (391). In the past, numerous CLL cases have been reported to carry t(11;14) (q13;q32), but these cases are now considered to represent a distinctly different lymphoid malignancy, namely MCL (398). Another translocation involving 14q32 is the t(14;19) (q32;q13). The breakpoint junction in CLL patients with this translocation was cloned and the gene on chromosome 19 was called *BCL3* (401). Rearrangements of the *BCL2* gene are found to be rare in CLL, but this gene is overexpressed in more than 85% of cases. Because *BCL2* is a potent inhibitor of apoptosis it may also contribute to CLL pathogenesis.

#### 75.13.5 MicroRNA and Epigenetic Dysregulation in CLL

MicroRNAs are short 19–25 nucleotide (nt) RNA that are processed from much longer primary transcripts

(called pri-miRNA with hundreds to thousands of nucleotides) and arise from hairpin loop structures (called pre-miRNA, 60–110 nts) after successive enzymatic maturation steps in the nucleus and in the cytoplasm (402). miRNAs bind primarily to the 3' UTRs of their target transcripts and thus reduce the levels of their target transcripts and the amount of protein encoded by the transcripts. It has been shown that miRNAs are involved in many important biological processes, including development, differentiation, metabolism, cell cycle regulations, and apoptosis, and in various cancers (44).

As described above, a homozygous or heterozygous deletion of the long arm of chromosome 13 is among the most common genomic abnormalities in CLL. Recently, miR-15a and miR-16-1 located in the minimally deleted regions at 13q14.3 have been found to be expressed highly in CD5 positive cells and reduced in CLL, high-grade B-cell lymphoma, myeloma, and other cancer cells (44,403,404). Both microRNAs are located in a region of exons 2 and 5 of the LEU2 gene, and it is proposed that the loss of both microRNAs is an early event in the pathogenesis of CLL (218). Both miR-15a and miR-16-1 negatively regulate BCL2 at a post-transcriptional level, and thus induce apoptosis in leukemia cells (405). Furthermore, a unique microRNA profiling for CLL was established that is associated with poor prognostic factors, such as IG Vh mutations and ZAP70 expression, and with disease progression in CLL (406). Higher miR-15a and miR-16-1 expression is associated with de novo aggressive CLL, and can affect chemotherapy potency and lead to drug resistance. There are many novel and promising discoveries of microRNA in CLL and other cancers, and some of these new biomarkers have become therapeutic targets on clinical trials (48,397).

### 75.13.6 Multiple Myeloma

As in CLL, the application of molecular cytogenetic tools, such as FISH and microarray techniques, has led to the discovery of numerous chromosomal abnormalities in MM, its precursor monoclonal gammopathy of undetermined significance (MGUS), and plasma cell leukemia (407). These chromosome and genomic abnormalities apparently occur stepwise following two different pathways involved in the pathogenesis of MGUS and MM (see below). In MM, abnormalities of the *IGH* locus in various chromosome translocations are found in about 40% of cases. *IGH* translocations deregulate the expression of oncogenes located near the translocation breakpoints, and are detectable by interphase FISH analysis in 50% of patients with MGUS, 60–75% of patients with MM, and more than 80% of patients with plasma cell leukemia (407). Five recurrent chromosome translocations have been observed and are associated with various prognoses. The t(11;14)(q13;q32) is found in 16% of cases, and results in the IgH/CCND1 fusion. The t(4;14)(p16;q32) is noted in about 15% of patients and deregulates the expression of the fibroblast growth

factor receptor 3 gene (*FGFR3*) and *MMSET* on the der(4) chromosome. The t(14;16)(q32;q23) is present in about 5% of cases and involves the juxtaposition of *IGH* and *MAF* (v-maf musculoaponeurotic fibrosarcoma oncogene homolog). The t(6;14)(p21;q32) is detected in about 3% of MM patients and leads to CCND3 overexpression. The t(4;14) and t(14;16) are associated with a poor clinical outcome, whereas the t(11;14) and t(6;14) confer a more favorable prognosis. Approximately 50% of patients with MM have a hyperdiploid clone with gain of chromosomes 3, 5, 7, 9, 11, 15, 19, and 21. These gains can be seen alone or more frequently in combination. A hyperdiploid karyotype in MM is associated with longer survival as compared to translocations involving 14q32 (408). Interestingly, samples with a hyperdiploid karyotype very rarely have rearrangements of *IGH* suggesting that there are two mutually exclusive pathways for the development of MM. Loss of chromosome 13 or a del(13q) is the most frequently observed chromosomal loss in MM (40–50%) and confers a poor prognosis, in particular when detected by metaphase analysis (407). Interestingly, microarray analyses have revealed that *miRNA-15a* and *miRNA-16* display a range of expression patterns in MM, independent of the chromosome 13 status, indicating that genes other than *miR-15a* and *miR-16* may explain the prognostic significance of 13q14 deletions.

Recently, gene expression profiling analysis in MM showed dysregulated and/or increased expression of cyclin D1, D2, or D3 in all of the above genetic pathways virtually in all MM and MGUS patients (407,409). Cyclin D1 is bi-allelically dysregulated in a majority of hyperdiploid myeloma patients. Increased expression of one of the cyclin D proteins facilitates activity of CDK4 or CDK6, which then phosphorylates and inactivates RB so that E2F can facilitate G1>S cell cycle progression. During the progression of MGUS to MM, activating mutations of K- or N-RAS play a critical role, in cooperation with loss or deletion of chromosome 13. Subsequently, additional oncogenic events occur including MYC dysregulation, bi-allelic deletion of p18 and loss or mutation of p53 resulting in more advanced stages (410). Thus, MM actually covers several subgroups that have differences in early or initiating events, global gene expression patterns, bone marrow dependence, clinical features, prognosis, and response to therapy (411).

### 75.13.7 t(2;5)(p23;q35) and the *ALK/NPM1* Fusion in Anaplastic Large T-Cell Lymphoma

t(2;5) is one of a few recurring chromosome translocation identified cytogenetically in mature T-cell lymphoma. Patients bearing this translocation have a specific histologic pattern of diffuse pleomorphic large cell lymphoma often called malignant histiocytosis, phagocytic large T-cell lymphoma, Ki-1 positive lymphoma, or now anaplastic large cell lymphoma (ALCL) (412). The

lymphoma cells are CD30 positive with variable morphologic features. The genes involved in this translocation are the nucleophosmin gene (*NPM1*) on 5q35 and the anaplastic lymphoma kinase gene (*ALK*) on 2p23. *NPM1* is a ubiquitously expressed nucleolar protein that shuttles between the nucleus and cytoplasm. It is an important protein that is implicated in multiple functions, including ribosomal protein assembly and transport, control of centrosome duplication, and regulation of the tumor suppressor ARF. *ALK* encodes a tyrosine kinase of the insulin receptor superfamily that is normally expressed in the neural cells of intestine, testis, and brain but is silent in normal lymphoid cells (413–415). The *NPM1/ALK* fusion protein contains the *NPM1* oligomerization motif and the *ALK* catalytic domain; it is constitutively activated through autophosphorylation, and mediates malignant cell transformation in vitro and in vivo by activating downstream effectors, including STAT3. The fusion protein *NPM1/ALK* is able to transform NIH3T3 cells suggesting that activation of this kinase is the primary event in the transformation (416). The t(2;5) involving the *NPM1* gene causes cytoplasmic rather than nuclear localization of the *ALK* protein, which can be detected by immunohistochemistry studies. In addition to t(2;5), more than eight other chromosome translocations and inversions, such as t(1;2) (q25;p23), all resulting in up-regulation of *ALK*, have been reported in ALCL. Recently, *ALK* has been found to be a novel dependence receptor and is inactive in the absence of engaging ligand(s). Its expression results in enhanced apoptosis, whereas *ALK* activation, via a ligand-mediated engagement or as result of *ALK* fusion proteins, decreases apoptosis (413,415). Notably, the *NPM1/ALK* fusion induces *MYC* expression in all pediatric ALCL with t(2;5) and *ALK* expression, indicating that *MYC* may be a downstream target of *ALK* signaling (417). Patients with *ALK* expression and t(2;5) and other translocations have a significantly better prognosis than those without these genetic abnormalities.

## 75.14 MOLECULAR ANALYSIS OF RECURRENT CHROMOSOME ABNORMALITIES

### 75.14.1 How and When Consistent Translocations Occur

We do not know how consistent structural rearrangements occur, but there are at least two possibilities. The rearrangements may be random, but selection may act to eliminate the vast majority that do not provide the cell with a proliferative advantage. Alternatively, certain changes may occur preferentially and thus may be the ones we see. The detection of cells which may harbor gene rearrangements typical for leukemia or lymphoma, in individuals without any sign of malignancy, has become one of the most intriguing findings of recent

years (167,384). It should be noted, however, that in a majority of cases described a highly sensitive (one cell per  $10^6$ – $10^8$  of total number of cells) nested RT-PCR or nested PCR was used. In addition, a study has shown that *BCR/ABL*, *AML1/ETO*, and *DEK/NUP214* (a nucleoporin gene) genes are generated spontaneously in hematopoietic cell lines in culture after exposure to ionizing radiation. However, these cells fail to proliferate in a malignant fashion and they die. Earlier studies showed an association of chromosome rearrangements in tumor cells with fragile sites affecting one of the chromosome bands broken in the tumor cells; however, the contribution of fragile sites to tumorigenesis is very unclear (418). The recognition of leukemia/lymphoma associated fusion transcripts in healthy individuals has been an important discovery, but much remains to be learned about its biologic significance.

Genomic analysis of translocation breakpoints has shown that some occur within *Alu* sequences (419,420), whereas others occur near topoisomerase II sites or DNaseI hypersensitive sites (421–424). A number of chromosome translocation breakpoints, for example, t(12;21), identified in ALL patients have been mapped near extended tracts of alternating purine and pyrimidine residues (425). These segments are known to form a helical structure known as Z-DNA. These regions might be susceptible to DNA recombination events because these repeat regions are susceptible to “slippage” during DNA replication both in vitro and in vivo (426,427).

Many of the chromosome rearrangements in B- and T-cell tumors involve sequences used in the normal recombination mechanisms of the V-D-J segments of the immunoglobulin and T-cell receptor genes. The presence of heptamer and nonamer sequences in the non-immunoglobulin gene involved in the translocation, for example, *MYC* and *BCL2*, has been reported (428,429). However, myeloid cells do not express recombinase-activating gene (*RAG*), and so this mechanism cannot explain translocations in these cells.

An equally important question is, when in the multistage process of malignant transformation of a particular cell do translocations or other chromosomal aberrations occur? Some chromosomal changes occur as part of the further evolution of the malignant phenotype, for example, blast crisis of CML, and are therefore relatively late events. But what about the occurrence of the t(9;22) in CML, for example? Does the translocation occur in a single normal cell, which becomes the progenitor of the leukemic clone, or is there expansion of a clone, possibly a pre-leukemic one, in which a translocation occurs in one of these already abnormal cells? In 1985, Fialkow and Singer have presented detailed evidence supporting the latter proposal. It was shown that some *BCR/ABL* transcripts detected in normal leukocytes and in the non-CML cell lines have an aberrant structure owing to incorrect

junctions between *BCR* and *ABL* exons; such genes would encode truncated BCR/ABL proteins that would presumably not be able to promote a growth advantage (430).

From all the data discussed in this chapter, it is clear that additional mutations as yet unidentified are generally needed to transform a minimally affected cell into a truly malignant expansion cell. There are several lines of evidence for this proposal. First, Adams and Cory constructed transgenic mice whose cells all had a vector containing the *MYC/IGH* junction from a murine plasmacytoma (431). All cells contained this construct; however, the B-cell tumors that occurred in every animal were clonal. Second, rare families with an inherited predisposition to develop AML exist (432). Third, molecular studies of childhood ALL showed that specific chromosome translocations may originate prenatally, although frank leukemia develops months or years later (307).

We have already discussed possible causes for mutagenic genetic events leading to leukemia development, and it is very likely that different causal mechanisms are at play in different patients. It is also important to consider genetic predisposition, which is poorly understood in the hematologic malignancies.

### 75.14.2 Specificity of Chromosome Rearrangements

The evidence presented in this chapter clearly demonstrates the remarkable specificity of certain chromosome rearrangements for particular subtypes of tumor, especially leukemia or lymphoma. The mechanism(s) by which this specificity is achieved is(are) unknown; however, a number of investigators have shown that certain proteins required for the promotion of gene expression are synthesized in a very cell-type specific manner. These proteins are only present in the appropriate cell type, and therefore the particular gene is activated only in that cell type. The chromosome rearrangements affecting *MYC* in B- and T-cell tumors strongly support the interpretation that the specificity resides in the gene that is uniquely active in a particular cell type (433). Thus the immunoglobulin genes are highly regulated in B cells and can, therefore, serve as the switch or activator mechanism for *MYC* in B cells; on the other hand, *TCRA* is an active gene in T cells with a strong enhancer and promoter and is clearly an activator for *MYC* in T cells. A reasonable paradigm is that translocations bring together in an inappropriate manner a growth factor, a growth factor receptor gene, or a transcription factor adjacent to an active cell-specific gene. It should be emphasized that some of these genes, which have been called proto-oncogenes, were identified as oncogenes in viruses that cause tumors. However, these genes have not been conserved through evolution from yeast and *Drosophila* to the chicken, mouse and humans solely to cause cancer.

### 75.14.3 Biologic Consequences of Consistent Chromosome Abnormalities

Cloning of many of the chromosome translocation breakpoints and the identification of the involved genes has had a major impact on our understanding of at least one critical event in the transformation of a normal cell to a leukemic one (434). The translocations in the lymphoid leukemias and lymphomas that involve the immunoglobulin genes in B-lineage tumors and the T-cell receptor genes in T-lineage tumors result in inappropriate expression of the other gene in the translocation, with no alteration in its protein structure. In contrast, all of the translocations cloned to date in the myeloid leukemias result in a fusion mRNA and a chimeric protein. This same situation is true for the t(1;19), t(4;11), t(11;19), and t(12;21) in ALL.

Cloning of the translocation breakpoints has led to the identification of a large number of new genes. It has been pointed out repeatedly that most of the genes cloned from the breakpoints in acute leukemia have been transcription factors, for example, *MYC*, *AML1* (*RUNX1*), and others. The *MLL* gene, however, appears to be involved in maintaining the chromatin structure of a gene in a more open configuration to allow transcription. These are so-called architectural genes, whose function involves modifying the chromatin conformation of genes, rather than altering the level of gene expression. Moreover, many of the translocation partners of *MLL* are normally part of the same large protein complex containing *MLL*, which is bound to DNA. This complex is involved in the regulation of the rate of mRNA transcription from the target gene. Thus, to have a critical partner present in a translocation appears to lead to a substantial growth advantage for cells containing the *MLL* fusion gene. Our new sophistication regarding the genetic changes in hematologic malignant diseases provides us with some very critical new diagnostic tools (12). Standard Southern blot analysis of tumor DNA can reveal clonal genomic rearrangements of genes using the appropriate probes. PCR can increase the sensitivity of detection of these aberrations; sometimes the sensitivity is too great to be clinically applicable. The development of gene expression array and genomic SNP microarray technology provides a powerful tool to analyze a tumor sample for measuring gene expression dynamics at various disease stages, for novel genomic alternations including gains and losses of genes, and for CN-LOH (31,38). cDNA and microRNA expression microarray technology classifies tumors based on their gene expression profiles. This allows for the characterization of tumors by the biologic pathways that are disrupted and or deregulated as opposed to primary DNA abnormalities. In some cases expression profiles could be used to identify patients who were likely to fail therapy or develop secondary disease (435,436). Genomic SNP microarray

techniques have greatly enabled us to detect subtle genomic imbalances and CN-LOH in various tumor cells, such as *PAX5* and *IKZF1* deletions in ALL.

Our increasing precision in identifying the genetic changes in the malignant cells comes at a most opportune time, because physicians will soon be in a position to use targeted therapy aimed at the specific genetic defect in the malignant cells. To use this targeted therapy effectively requires a precise genotype of the malignant cells. Two very powerful examples of targeted therapy are the use of ATRA in APL and of Imatinib (Gleevec) in CML. Although a number of genes will be affected in various genetic alterations leading to a tumor cell, those involved in chromosomal changes may be among the easiest to monitor and the most effective to treat.

#### 75.14.4 Cooperation of Multiple Genetic Abnormalities in Leukemogenesis and Lymphomagenesis

As described above, there are many acquired recurring chromosomal abnormalities and gene mutations in leukemia and lymphoma. Some of these aberrations are unique with a strong association with clinical and morphological features. From various transgenic mouse models, it is assumed that most of these genetic abnormalities alone are not sufficient in inducing leukemia and lymphoma. Coexistence of different genetic changes, such as chromosome translocations that usually result in loss of function or mutations of transcription factors and gene mutations involving tyrosine kinases, suggests that these aberrations cooperate in oncogenesis. As described in the earlier sections in AML, the t(8;21) or inv(16)/t(16;16) and *c-KIT* mutations are common in CBF leukemia, and *FLT3* mutations in AML with other recurring chromosome translocations. In patients with Down syndrome, Look et al. reviewed the interactive mechanism of the *GATA1* mutations with trisomy 21 in leading to acute megakaryoblastic leukemia. Gilliland et al. proposed a hypothesis of “two-hit” model that at least two classes of mutations are involved to transform a normal HSC into a clonal AML. Class I mutations are activating mutations that confer proliferative and/or survival advantage to hematopoietic progenitors, but do not affect differentiation (437–439). It commonly involves genes of tyrosine kinases pathways, such the *BCR/ABL1* fusion in CML, and the *TEL/PDGFRB* in CMML, *JAK2* point mutations in MPN, and *KIT* and *FLT3* activating mutations in AML, and genes in the *RAS/BRAF* pathway in AML and MDS. These constitutively activated tyrosine kinase genes provide several therapeutic targets with tyrosine kinase inhibitors, such as Imatinib in CML. Class II mutations result in loss of function of those genes that are transcriptional factors and tumor suppressor genes, and serve primarily to impair hematopoietic differentiation and subsequent apoptosis, such as the *AML1/ETO* and *CBFB/MYH11*

fusion in CBF leukemia, the *PML/RARA* fusion in APL, translocations involving *MLL* and *EVII1*, mutations in *CEBPA* and *NPM1* in AML and MDS, and the *TEL/AML1* fusion in ALL. This hypothesis has been validated in acute leukemia evolving from MPN. In MPN, leukemia cells carry various mutations, such as *JAK2* and *PDGFRA/B*. The clinical course is usually mild with a long latency to evolving to acute disease. To generate overt leukemia, a second class of genetic alterations must produce lineage-specific blocks in differentiation, such as translocations and deletion and duplications that involve genes encoding chimeric transcription factors produced by chromosomal translocation. The most common cooperation mutations in myeloid leukemia are mutations between *AML1* and *RAS*, *NPM1* and *FLT3*, and *MLL* and *BRAF* (440–442).

The last few years has revealed many mechanisms related to the epigenetic regulation of genes, such as microRNAs (discussed in the CLL section) plus histone modification at both the DNA and RNA level (42). Many of the partner genes of common AML translocations such as *ETO* and *PML* are repressed through their association with HDACs and their repression passes to the partner fusion gene *AML1/RUNX1* or *RARA* which has critical function related to cell growth and differentiation (194,442,443). The next revolution is likely to involve more RNA species about which we are ignorant, as well as a more sophisticated understanding of the role of protein modification in the cell. Finally, we pay little attention to lipids, to the regulation and interaction of cell organelles, of scaffold proteins, and their essential roles in protein transport and intra- and intercellular signaling. Although we have made enormous progress in the last five or six decades, we have a long way still to go before we will be equipped to monitor the critical changes in each tumor that will allow us to really practice personalized medicine. Using novel techniques, such as microarray of genomic DNA, gene expression and microRNA, and next generation sequencing, many novel genetic abnormalities will be found in leukemia and lymphoma, as well as in other solid tumors of epithelial cell origin (135,379,415). We will better understand the genetic mechanism of oncogenesis and thus provide more powerful and personalized treatment options.

### Biographies

**Dr Janet D Rowley** is Blum-Riese Distinguished Service Professor of Medicine, Molecular Genetics and Cell Biology, and Human Genetics, Pritzker School of Medicine, University of Chicago. She earned a Bachelor of Philosophy degree (1944), a Bachelor of Science degree (1946) and a Doctor of Medicine degree (1948) from the University of Chicago.

A faculty member at the University of Chicago since 1962, Dr Rowley is internationally renowned for her studies of chromosome abnormalities in human leukemia and lymphoma. In 1972, she discovered the first consistent chromosome translocation in any human cancer, the t(8;21) in AML. In a landmark paper in 1973, Dr Rowley described the t(9;22) in CML. Subsequently, she identified more than a dozen different recurring translocations in children and adults with leukemia and lymphoma. Her discoveries have resulted in more accurate diagnostic techniques and the development of effective treatment protocols targeted to particular genetic abnormalities, such as Imatinib for CML.

Dr Rowley is a member of the National Academy of Sciences, the Institute of Medicine, the American Philosophical Society, and the American Academy of Arts and Sciences. She was awarded the 2011 Ernest Beutler Lecture and Prize from the American Society of Hematology, the Seventh Annual AACR Award for Lifetime Achievement in Cancer Research in 2010, the 2009 Presidential Medal of Freedom, the 1998 Albert Lasker Clinical Research Award, the 1998 National Medal of Science, and the 1989 Charles S. Mott Prize from General Motors Cancer Research Foundation.

**Dr Yanming Zhang** attended a medical school in China in the early 1980s, and received his MD degree in 1994 in Germany. He did postdoctoral research training in cytogenetics in non-Hodgkin lymphoma in Kiel, Germany from 1995 to 1998, and continued on characterizing genomic breakpoints and the mechanisms of chromosome translocations in AML under Dr Janet D Rowley's guiding at the University of Chicago between 1999 and 2002. Later Dr Zhang finished a 2-year clinical cytogenetics fellowship training that was accredited by the American Board of Medical Genetics, and became a board certified clinical cytogeneticist. From 2005 to 2010, he was Assistant Professor of Medicine, and served as Assistant and Associate Director with Dr Michelle M Le Beau as Director in the Cancer Cytogenetics Laboratory at the University of Chicago. Since 2011, Dr Zhang is Associate Professor of Pathology at Northwestern University, Medical Director of newly established Cytogenetics Laboratory at Northwestern Memorial Hospital, and a member of R. Lurie Comprehensive Cancer Research Center at Northwestern University. Dr Zhang's research interests are to clarify the mechanisms of recurring chromosome translocations in leukemia and lymphoma and to study genomic imbalances in cancer using genomic microarrays and other molecular techniques.

### 76.1 INTRODUCTION

Autoimmunity is a breakdown of the normal mechanisms that maintain immunologic homeostasis in the immune response to specific antigens. The pathology of autoimmune disease is multifactorial, including both genetic and environmental factors affecting the onset, maintenance, and progression of the disease (1–6). Autoimmune diseases result from the recognition of self antigen(s) and the subsequent attack of self-tissues, usually by the adaptive immune response. Autoimmune pathology can be caused by T lymphocytes, natural killer (NK) cells, and/or antibodies and can be modulated by hormonal effects. One of the unifying themes of many autoimmune disorders is that they are associated with specific alleles and genotypes of the highly polymorphic major histocompatibility complex (MHC) where, in humans, the human leukocyte antigen (HLA) loci reside. Since the completion of the human genome project in April 2003 (<http://www.genome.gov/10001772>), a plethora of new information about the genetics of autoimmune disease has allowed the identification of a number of new genes involved in autoimmunity. The aim of this chapter is to present an update of recent genetic associations of autoimmunity with common genetic variants obtained through the genome-wide association studies (GWAS) and how these data have changed our knowledge of selected diseases, which historically showed an association with HLA (7,8).

### 76.2 THE IMMUNE RESPONSE

#### 76.2.1 The Adaptive Immune System

In general, the mechanisms that produce tissue damage and clinical disease in autoimmune disorders are the same as those that mediate protection from pathogens. The immune system consists of a system of interacting molecules and cells that function to (1) recognize intracellular and extracellular threats (primarily pathogens); (2) alert and activate lymphocytes, monocytes and NK cells for specific response to these threats; (3) commit the responding cells to an appropriately regulated response to the threat; (4) amplify the response, if necessary, by recruitment of additional cells, including polymorphonuclear (PMN) leukocytes and macrophages, as well as additional lymphocytes and monocytes; and (5) ultimately, terminate the specific immune response after the threat has resolved.

The major components of the human adaptive immune response consist of antigen presenting cells (APC), T lymphocytes, B lymphocytes, HLA molecules, peptides, and costimulatory molecules. An immune response occurs when a peptide bound to an HLA molecule is recognized by a T-cell receptor (TCR), a phenomenon known as *antigen presentation*. The specific peptide, HLA molecule, and T cell together determine the nature of the response. There are two general categories of HLA molecules that perform this antigen presentation function: class I molecules (e.g.

A, B, and C) and class II molecules (e.g. DR, DQ, and DP), each class having a different tissue distribution.

X-ray crystallographic structural studies have revealed that the outer domains of both class I alpha-chain molecules and the class II alpha-beta heterodimers form a peptide-binding groove, consisting of a beta-pleated sheet floor and two alpha-helical walls (9,10). Typically, the peptides bound in class I clefts are octamers or nonamers with the ends of the peptide buried within pockets of the cleft (11). CL-II peptides bound in the class II groove are somewhat longer, usually 12–14-mers, with the ends protruding from the cleft. The extensive polymorphism in HLA molecules lies primarily in the amino acids forming the floor and sides of the groove. The topography of the groove is unique for each allelic group of HLA molecules. Because only certain amino acid residues can “fit” into certain pockets based on size and charge, the peptides that can be bound by any given HLA molecule are limited. Some polymorphic residues within the HLA binding groove bind to the peptide, whereas others bind to the T-cell receptor (12). The structure and the capacity of HLA molecules to bind different peptides differ widely among different individuals owing to the extensive genetic polymorphism of the HLA genes, accounting for the association between genetic polymorphisms and variable immune response (13–16). Thus, it is the specific combination of a peptide–HLA complex that provides the genetically controlled determinant of antigen-specific recognition.

It is the complex of specific peptide bound within a given HLA antigen that is recognized by the TCR. The TCR of CD4 T cells generally recognize peptide in the context of class II molecules to provide T-cell help (Th). These T helper cells can be of at least two different types. In general, Th1 cells provide help to other T cells (CD8) to affect cell killing. Th2 cells provide help to B cells in the production of antibody. By virtue of the cytokines they release, Th1 cells are predominantly inflammatory, whereas Th2 cells can often inhibit the inflammatory response. However, Th2 cells can contribute to an overproduction of antibody, which is a pathologic feature of some autoimmune diseases. In contrast, the TCR of CD8 T cells generally recognize peptide in the context of class I molecules. These cells perform target cell killing and are known as cytotoxic T lymphocytes (CTL). In addition, a subpopulation of both CD4 and CD8 T cells can carry out a regulatory (suppressive) role, in which case they are referred to as T-regulatory cells (TR or Tregs). These latter cells are CD4+CD25+FOXP3+ or CD8+CD25+/-FOXP3+. The Tregs (2–10% of the circulating T cells) are essential in the maintenance of normal tolerance to self antigens. Dysregulation of the Tregs can lead to profound autoimmunity (17–19).

In the adaptive immune system, a specific immune response is initiated when a peptide bound to an HLA class II molecule on the surface of an APC, such as a macrophage or dendritic cell, is recognized by the T-cell receptor on a CD4 T lymphocyte, which is specific for the peptide–HLA molecule complex. T-cell activation

results from this antigen-specific recognition event, provided a costimulatory interaction between B7 molecules (also known as CD80 and CD86) on the APC and CD28 on the T cell has also occurred (see Section 76.4.2).

## 76.2.2 The Innate Immune System

NK cells are one of the first lines of defense of the innate immune system, functioning before initiation of the adaptive immune response, as well as when the latter system is subverted, as happens in some viral infections and cancer and likely in autoimmunity (20). Regulation of NK cytolytic activity is a function of engagement of one or more NK surface receptors that may be activating or inhibitory. Two of the primary sets of receptors present on human NK cells are called the killer immunoglobulin-like receptor (KIR) and the CD94/NKG2 lectin-like receptors (21–23). They each are comprised gene families. The KIR genes (15 genes, 2 pseudogenes) located on chromosome 19q13.4 have enormous genetic diversity generated by a combination of variable gene content on any given haplotype, alternative splicing, and allelic polymorphism, and they recognize a limited set of HLA Class I molecules or epitopes. The more ancestral CD94/NKG2 genes (four genes plus NKG2D) located on chromosome 12p12.3–p13.2 have less diversity but an unconventional array of HLA Class I-like ligands. The ligands for the KIR are the HLA classical Class I molecules A, B, C and the nonclassical Class I, HLA-G. HLA Class II does not appear to be involved. The CD94/NKG2 and NKG2D ligands are generally HLA Class Ib molecules such as HLA-E or stress inducible nonclassical HLA Class I-like molecules such as MICA and MICB [MHC Class I-related chain] proteins (24). In the innate immune system, *de novo* recognition of self antigens can occur when cryptic epitopes become exposed due to cell death/apoptosis (25) and can lead to autoimmune disease (see Section 76.3).

## 76.3 AUTOIMMUNE PATHOLOGY

Autoimmunity is thought to involve the activation of a self-peptide-specific T cell or NK cell, leading to the development of autoreactive CTLs, the inappropriate activation of macrophages, and the release of cytokines as well as inappropriate T-cell help, resulting in the formation of antibodies to self antigens. Autoimmune tissue damage is mediated by autoantibodies, autoreactive T cells, or NK cells. Autoantibody-mediated disorders are distinguished by the different types of antigens that are recognized and the different classes of immunoglobulin that result in disease. Allergic (atopic) reactions are mediated by the production of IL-4 by CD4 Th2 cells, leading to the production of immunoglobulin E by B cells, in response to extrinsic (not self) antigens. The IgE can bind to and activate mast cells via the Fcε R1, releasing histamines, and other mediators and causing clinical symptoms, such as asthma or allergic rhinitis (hay fever). Some autoimmune diseases result from the production of IgG antibodies in response to self

**TABLE 76-1** Selected Autoimmune Diseases and Associated HLA Alleles

Disease	Associated HLA Alleles
<b>Organ-specific (endocrine)</b>	
Type 1 diabetes	DRB1*03:01–DQB1*02:01; DRB1*04:01–DQB1*03:02 <sup>a</sup> DRB1*03:01–DQB1*02:01; DRB1*04:01–DQB1*03:02 <sup>a</sup>
Graves' disease	DRB1*03:01–DQB1*02:01
Hashimoto's thyroiditis	DRB1*11–DQB1*03:01
Idiopathic Addison's	DRB1*03:01–DQB1*02:01 disease
<b>Organ-specific (other)</b>	
Inflammatory bowel	DRB1*01:03–DQB1*05:01; disease DRB1*01:03–DQB1*03:01
Crohn's disease	DRB1*11:01
Ulcerative colitis	DRB1*11:01
Myasthenia gravis	DRB1*03:01–DQB1*02:01
Multiple sclerosis	DRB1*15:01–DQB1*06:02
Psoriasis vulgaris	C*06
Pemphigus vulgaris	DRB1*04:02–DQB1*03:02; DRB1*14:01–DQB1*05:03
Narcolepsy	DQB1*06:02
Celiac disease	DQA1*05:01–DQB1*02:01 (in cis or in trans; see text)
Dermatitis herpetiformis	DQA1*05:01–DQB1*02:01
<b>Rheumatologic diseases</b>	
Rheumatoid arthritis (RA)	DRB1*04–DQB1*03:02 <sup>b</sup> ; DRB1*01– DQB1*05:01; DRB1*10– DQB1*05:01
Pauciarticular juvenile RA	DRB1*08–DQB1*04:02; DRB1*11– DQB1*03:01, DPB1*02:01
Ankylosing spondylitis	B*27
Reactive arthropathy,	B*27 including Reiter's disease
Systemic lupus	DRB1*03:01–DQB1*02:01 <sup>c</sup>
erythematosus (C4A null allele)	DRB1*15:01–DQB1*06:02

<sup>a</sup>Not all DRB1\*04 alleles confer equal risk for type 1 diabetes; DRB1\*04:03 and \*04:06 are protective, whereas the highest risk DRB1\*04 alleles are 04:01,04:02, and 04:05. The highest risk genotype is DRB1\*03:01–DQB1\*02:01/DRB1\*04–DQB1\*03:02 (see text).

<sup>b</sup>Not all DRB1\*04 alleles confer equal risk for RA; DRB1\*04:01 and 04:04 and 04:05 appear to confer the greatest risk. These alleles also appear to be associated with the severity of disease, unlike the disease-associated DRB1\*01 and DRB1\*10 (see text).

<sup>c</sup>The DRB1\*03:01 association with SLE is likely due to linkage disequilibrium with the C4A null allele on B\*08-DRB1\*03:01 haplotypes (see Section 76.7.9).

antigens, such as cell-surface receptors. The autoantibody can disrupt the normal function of the receptor by causing uncontrolled activation (agonist) or by blocking receptor function (antagonist) and signaling. In Graves' disease, autoantibodies to the thyroid-hormone-stimulating receptor cause activation and hyperthyroidism, whereas in myasthenia gravis, autoantibodies to the acetylcholine receptor disrupt function and cause progressive muscle weakness. Some antibody-mediated autoimmune diseases, such as pemphigus vulgaris (PV), involve the production of IgG in response to cell- or matrix-associated antigens (the skin matrix protein, desmoglein 3 for PV), leading to tissue damage (blistering of skin and mucosal membranes for

PV). Another form of antibody-mediated disease, such as systemic lupus erythematosus (SLE), reflects the production of antibodies to soluble antigens subsequent to exposure to cryptic autoantigens. In these diseases, the tissue damage is caused by responses triggered by immune complexes. A selected set of autoimmune diseases and their associated HLA alleles are listed in Table 76-1 and the putative autoantigens and pathogenic immunological mechanisms for some of these diseases are listed in Table 76-2.

In most autoimmune diseases, the environmental trigger or the eliciting antigen is not known. In some autoimmune diseases, infection with specific pathogens may represent an environmental trigger, eliciting an autoimmune response in genetically predisposed individuals. There are several hypothetical mechanisms by which infectious agents could break tolerance and induce auto-reactive responses, such as molecular mimicry, release of cryptic self antigen, and activation of nontolerized cells, among others. Although epidemiologic studies may ultimately reveal the role of an infectious environmental trigger, direct evidence for the initiation of autoimmunity by an infectious agent is still lacking for most human autoimmune diseases.

## 76.4 AUTOREACTIVE T CELLS AND THE FAILURE OF TOLERANCE

The maturation of T cells in the thymus involves positive selection as well as negative selection (deletion of self-reactive T-cell clones). The presence of autoreactive T cells in autoimmune disorders indicates that this latter process is not complete. Current consensus is that only the highest affinity self-reactive T cells are deleted in the thymus. Thus, self-reactive T cells with lower affinities may escape negative selection, as well as T cells specific for self peptides that are not expressed in the thymus. These autoreactive T cells may, under normal conditions, be prevented from mediating autoimmune disease by never encountering the relevant antigen or by being in a state of Treg-induced quiescence or by some other unknown regulatory mechanisms. But environmental triggers, such as infection, may disrupt these mechanisms in genetically predisposed individuals.

### 76.4.1 Thymic Education: Positive and Negative Selection

The diversity of TCR specificities creates a broad functional potential for antigenic recognition, an essential component of the adaptive immune response. By chance, TCR specificities, which are potentially reactive with self antigens, are also created during random TCR gene rearrangement, creating the potential for autoreactive T cells. In the normal course of T-cell maturation, however, several TCR selection steps are designed to protect the individual from expression of such autoreactive T cells. This pathway of T-cell development is called

**TABLE 76-2 Selected Autoimmune Diseases and Autoantigens**

Disease	Immunologic Mechanism	Putative Autoantigen	Clinical Consequences
Graves' disease	Antibody to cell surface receptor (agonist)	Thyroid stimulatory hormone receptor (TSH)	Hyperthyroidism
Myasthenia gravis	Antibody to receptor (antagonist)	Acetylcholine receptor	Progressive muscle weakness
Pemphigus vulgaris	Antibody to skin protein	Epidermal cathedrin (desmoglein 3)	Blistering of skin and mucosal membranes
Type 1 diabetes	T-cell mediated	Insulin, GAD (glutamic acid decarboxylase), Insulin antibodies (IA-2), Islet cell antibodies (ICA)	$\beta$ -cell destruction, insulin insufficiency
Rheumatoid arthritis	T-cell mediated	Unknown synovial antigen	Inflammation and destruction of joints
SLE (systemic lupus erythematosus)	Deposition of immune	DNA, histones, small nuclear ribonucleoproteins (SnRNP), small cytoplasmic ribonucleoproteins (ScRNP), ribosomes	Arthritis, glomerulonephritis, vasculitis
Narcolepsy	Autoantibodies	Hypocretin, Tribbles Homolog 2 (TRIB2)	Excessive sleepiness

*thymic education* because it occurs predominantly in the thymus, the site of T-cell maturation.

After expression of rearranged TCR genes, immature T lymphocytes in the thymus are capable of receiving antigen-specific signals from HLA–peptide complexes expressed on APCs. Early in the maturation process, such T cells encounter HLA–peptide complexes presented by thymic epithelial cells arrayed in the thymic cortex. In a process known as *positive selection*, T cells at this immature stage receive growth and differentiation signals as a result of TCR ligation. T cells with rearranged TCR capable of reacting with self HLA and self peptide complexes continue to develop and mature (26). T cells with TCR that do not recognize self HLA–peptide complexes die within the thymus. This positive selection of T cells based on HLA–peptide recognition is responsible for the phenomenon known as *MHC restriction*, wherein T cells specific for a given peptide recognize that peptide only in the context of a particular HLA molecule. Thus, following TCR alpha and beta gene rearrangement, CD4, CD8 double-positive, immature T cells are positively selected to become single positive and restricted to either specific class I molecules (CD8 T cells) or specific class II molecules (CD4 T cells).

After positive selection, the T cells traffic to the thymic medullary areas, where they encounter HLA–peptide complexes expressed on a different type of APC, namely, hematopoietically derived monocytes and dendritic cells similar to the types of mature APCs used by the peripheral immune system to respond to antigenic challenge. In the thymic medulla, these immature T cells can proceed through one of the four developmental routes. One, when they encounter very strong antigenic signals from the HLA–peptide complex, an apoptosis (programmed death) response is triggered that results in the deletion or negative selection of these strongly autoreactive cells. Two, they can undergo receptor editing to display a receptor that is not, or is less strongly, self reactive. Three, they can become tuned or anergic, so they are less responsive to self antigens. Four,

T cells specific for self peptides that are not expressed in the thymus can exit the thymus as immunologically ignorant but potentially autoreactive and approximately 20–50% of the resulting TCRs are dangerously self reactive, requiring peripheral control (26). Experimental animal models of immune maturation have demonstrated that failure of this negative selection maturation step results in several types of organ-specific and systemic autoimmunity. A complex set of poorly characterized developmental regulatory genes controls this T-cell maturation pathway, some of which may contribute to human autoimmunity and aberrant immune response (27,28).

### 76.4.2 Breakdown of Immunologic Homeostasis or Equilibrium

The clonal deletion of autoreactive T cells in the thymus is only one of the mechanisms for preventing autoimmunity. In general, the adaptive immune response to a specific antigen is a dynamic and regulated process, reflecting the ability of the vertebrate immune system to maintain a “precarious equilibrium between the extremes of reactivity and quiescence” (reviewed in Reference (29)). The immune system has several fail-safe mechanisms to prevent aberrant or unregulated TCR activation, as well as several feedback mechanisms designed to guide pathways of T-cell commitment to specific effector functions. As a counter balance to immune activation, the immune system has several mechanisms for downregulating lymphocytes, and terminating an ongoing immune response. The disruption of these terminator pathways can result in uncontrolled immune amplification and autoimmune disease. Some mechanisms for lymphocyte regulation are mediated through cell surface intermolecular interactions, analogous to pathways used for activation. One of the most important of these pathways is the interaction between CTLA-4 molecules expressed on T lymphocytes and the CD80/CD86 molecules (B7) expressed on antigen presenting cells. The CTLA-4-B7 recognition

system acts as a counter balance to the CD28-B7 recognition system involved in T-cell activation. When the CTLA-4 protein is expressed on T lymphocytes and is activated by contact with the B7 molecule on APCs, it recruits phosphatases to the site of TCR activation complexes, which intersect and interrupt the kinase-mediated activation pathways, resulting in a negative, rather than a positive, signaling pathway (30). The lymphoid protein phosphatase (LYP), encoded by the gene PTPN22, is known to associate with the negative regulatory kinase Csk and to downregulate T-cell activation. The R620W polymorphic variant at this locus has been shown to be associated with a number of autoimmune diseases (see Section 76.7.7).

Another form of immune downregulation is mediated by the TNF cytokine family and by the Fas–Fas ligand set of cell surface ligands, leading to death of the target cells. These terminator effector pathways induce apoptosis, by triggering signaling cascades that activate death-mediating molecules such as caspases and that inhibit protective molecules such as BCL-2 (31). Yet another set of signal transducing cell surface molecules that can maintain homeostasis are the inhibitory and activating receptor systems on NK cells. In general, receptor systems on lymphoid and myeloid cells can result either in activation or inhibition depending on the structure of the cytoplasmic domain and the signals transduced when the receptor is engaged by the ligand. An appropriate balance between activation and inhibition signals seems to be required for normal immune modulation, by regulating initiation, amplification, and termination of specific responses. The absence of inhibitor signaling, as demonstrated in knockout mice with targeted disruption of inhibitory receptors, can result in autoimmune diseases and unregulated inflammatory responses (29).

## 76.5 GENETICS OF AUTOIMMUNE DISEASES

Familial clustering and comparisons of disease concordance among monozygotic and dizygotic twins clearly indicate that a variety of autoimmune diseases have a strong genetic component. Unlike the case of monogenic diseases caused by mutations, the alleles and genotypes that predispose to most autoimmune diseases are present in normal healthy individuals and generally only a minority of individuals with the high-risk genotypes actually gets the disease. Most autoimmune diseases are thought to be polygenic with a significant environmental component. In principle, polymorphism in any of the genes that encode elements in the T-cell activation pathways described earlier could play a role in genetic predisposition to specific autoimmune diseases. Linkage analysis studies have been used until recently to study possible transmission of two or more linked genes on a chromosome. Studies of autoimmune disease in families show some familial aggregation but the linkage analysis is generally of a low power. A linkage analysis study is feasible only if the genetic component of the disease is strong and samples are available from relevant family members.

Several historic studies indicate many autoimmune disorders that show linkage to and/or association with genes in the MHC and specific alleles of the HLA loci. The HLA region on the short arm of chromosome 6 (6p21.3), spans 3.6 Mb and contains approximately 200 genes, many of which are involved in immune function (32–34). Both the HLA class I and class II genes encode highly polymorphic cell surface molecules that bind and present processed antigens in the form of peptides to T lymphocytes. Recognition by the T cell of the HLA–peptide complex, along with a costimulatory signal, results in T-cell activation. The class I molecules HLA-A, -B, and -C are found on the surface of most nucleated cells, presenting peptides primarily derived from endogenously synthesized proteins (e.g. self, viral, and tumor peptides) to CD8 T cells. These heterodimers consist of an HLA-encoded alpha chain associated with a monomorphic polypeptide, beta-2 microglobulin, encoded on chromosome 15.

The HLA class II molecules consist of HLA-encoded alpha and beta chains associated as heterodimers on the cell surface of antigen presenting cells such as B cells, macrophages, and dendritic cells. Class II molecules HLA-DR, DQ, and DP serve as receptors for processed peptides, derived predominantly from membrane and extracellular proteins (e.g. self and bacterial peptides) and are presented to CD4 T cells. Both the HLA-DQ and DP regions contain one functional gene for each of their alpha (DQA1 and DPA1) and beta (DQB1 and DPB1) chains, as well as the pseudogenes DQA2, DQB2, DPA2, and DPB2. The HLA-DR region, however, contains one functional gene for the alpha chain (DRA), but either one or two functional genes for the beta chain, depending on the haplotype. All individuals express a DRB1 encoded polymorphic polypeptide that is found on the cell surface in association with the monomorphic alpha chain. The other functional class II DRB genes DRB3, DRB4, and DRB5 encode a beta chain that forms a second cell surface heterodimer with the DRA-encoded alpha chain. In general, the DRB3 locus is found on haplotypes where DRB1 is \*03 (comprising the serologic subtypes DR17 and DR18), \*11, \*12, \*13, or \*14; the DRB4 locus is found on haplotypes where DRB1 is \*04, \*07, or \*09, and the DRB5 locus is found on haplotypes where DRB1 is \*15 or \*16 (corresponding to the serological subtypes DR15 and DR16 of serologic type DR2). DRB1\*01, \*08, and \*10 haplotypes typically have only the DRB1 locus.

Many other genes with important immune functions are found within the MHC. In the class III region, between the HLA-DR region (class II) and the HLA-B locus (class I), are found the complement genes encoding C2 and C4, as well as the TNF-alpha and -beta loci. The MICA and MICB loci (see Section 76.7.9), are located just centromeric of HLA-B. The TAP1 and TAP2 loci are located between the DQ and DM loci.

The TAP loci encode the peptide transporter molecules involved in loading the newly synthesized class I molecules in the ER with peptides derived from proteolysis of proteins in the cytoplasm by the proteasome. The LMP2 and LMP7 genes, located near the TAP loci, encode the  $\gamma$ -interferon-inducible subunits of the proteasome. HLA-E and HLA-G are class I loci, whose polymorphism and tissue distribution are both much more limited than those of the classical HLA-A, B, and C genes. The HLA-G genes appear to be particularly important in pregnancy, where they are expressed at the maternal–fetal interface of the cytotrophoblast (35). There are many other genes within the MHC, whose function has not yet been elucidated. In general, these loci are all much less polymorphic than the HLA class I and class II loci.

## 76.6 HLA ALLELIC DIVERSITY AND POPULATION GENETICS

The HLA class I and class II genes are the most polymorphic coding sequences in the human genome. The total number of HLA alleles for all the loci, was of 6403 as April 2011 (The International Immunogenetics Project (IMGT)/HLA Database). Virtually all of this extensive sequence diversity is localized, for the class I loci, in the second and third exons, and for the class II loci, in the second exon. For the class I molecule, the peptide-binding groove is formed by a single chain with the beta-pleated sheet floor and two alpha-helical walls being encoded by the second and third exons. The class II polymorphic second exons encode the outer domains of the alpha and beta chains, which, together form the characteristic peptide-binding groove.

The patterns of allelic sequence diversity for both the class I and class II loci are highly unusual; some alleles differ in the polymorphic exons by as much as 15% and the sequence variation is distributed as a patchwork of localized polymorphic sequence motifs. The allelic diversity at these loci is thought to have been generated by recombinational mechanisms such as gene-conversion-like events or, to a lesser extent, by reciprocal recombination (33). Thus, new alleles appear to have been created by shuffling these discrete polymorphic sequence motifs. In addition, point mutation has contributed to sequence diversity at the HLA loci.

Although a very large number of alleles (e.g. >400 for HLA-DRB1) can be found in the global human population, a much smaller number (e.g. 30–50 for HLA-DRB1) is present in most individual populations. Many populations who have gone through bottlenecks or founding events (e.g. Native Americans) show more limited allelic diversity. In general, different populations tend to have different distributions of alleles as well as exhibit different patterns of linkage disequilibrium. Strong linkage disequilibrium is a striking feature of the genetics of the HLA region and can create difficulties in moving from an observed disease

association with an allele at one locus, to identifying a causal locus. In all populations, particular haplotypes consisting of specific alleles at the linked HLA loci are found much more frequently than would be expected at random. The linkage disequilibrium for this haplotype extends to the DPB locus, about 3Mb centromeric of HLA-A. Although a variety of evolutionary forces can create linkage disequilibrium, selection for particular combinations of HLA alleles has been suggested as the primary cause for these extended haplotypes. This strong linkage disequilibrium makes it difficult to assess which allele or which combination of alleles on a disease-associated HLA haplotype is responsible for observed correlations with disease. But the alleles found in linkage disequilibrium differ among various populations, disease association studies in many different ethnic groups can prove valuable in identifying the contributions of individual alleles.

## 76.7 GENETIC SUSCEPTIBILITY TO AUTOIMMUNE DISEASE

Linkage of genes within the HLA region to several different diseases has been demonstrated by cosegregation studies in families, or with nonparametric approaches such as haplotype sharing among affected sib pairs. The genetic region identified by linkage studies can be large, on the order of 5 cM (5% recombination). Higher resolution mapping of disease genes can be provided by disease association studies because these depend on strong linkage disequilibrium between the genetic marker and the disease allele. In general, the association of a marker with a given disease implies that the genetic marker is significantly <1 cM away from the disease gene. In case-control association studies, the frequency of a given genetic marker among unrelated patients is compared with the frequency in matched controls. Although many parameters influence linkage disequilibrium, such as population history, population admixture, the age of the marker and of the disease alleles, and so on, the strength of linkage disequilibrium is generally inversely related to physical distance. Thus, a strong association with a given disease, particularly if it is found in different ethnic groups, suggests either that the associated marker locus is very close to the disease locus or that it may itself confer susceptibility to the disease.

HLA alleles that are positively associated with disease are referred to as *susceptible*, whereas negatively associated alleles are termed *protective*. In heterozygote conditions in which one haplotype is susceptible and one is protective, protection is generally dominant. Table 76-1 lists a selected set of autoimmune diseases and their associated HLA alleles. Specific HLA alleles may enhance the autoimmune response by influencing immunogenicity thereby predisposing to autoimmunity by influencing the expressed repertoire of T cells.

These disease associations with specific HLA alleles have been demonstrated in numerous case-control

studies, as well as family studies in a large number of different populations (reviewed in Reference (36)). Most of these diseases are associated with alleles in the HLA class II region, but several diseases are associated with specific class I alleles. Some of the more common diseases associated with specific HLA alleles are listed below along with newer data of other genes that may also play a role in the disease process.

### 76.7.1 Ankylosing Spondylitis (AS)

There is a well-known correlation of HLA-B\*27 and AS. HLA-B\*27 is more common in northern Europeans and is rare in Africans and Australian Aborigines. Most studies reveal that 80–95% of AS patients are HLA-B\*27 positive. In white Europeans, the relative risk (RR) or odds ratio (see Section 76.7.8) for AS and B27 is well over 100. There are over 80 B27 alleles (see the Anthony Nolan Trust database, <http://hla.alleles.org>), some of which are sufficiently prevalent that a relative strength of their association with AS can be compared. There appears to be a hierarchy of associations with some B27 alleles and AS (reviewed in Reference (37)). HLA-B\*27:04 shows a stronger association than B\*27:05, B\*27:02, or B\*27:07, which in turn show a stronger association than B\*27:06 or B\*27:09. The reported total genetic risk for HLA-B\*27 and AS is 20–50%. Several theories have been proposed (reviewed in Reference (3)) to explain the HLA-B\*27 association with AS: HLA-B\*27 may present a microbial peptide that elicits a T cell response that cross-reacts with a self antigen; the HLA-B\*27 may misfold and thereby accumulating in the endoplasmic reticulum causing a cytokine response; and B\*27 heavy chains may be expressed at the cell surface as homodimers disrupting the normal HLA class I mediated response.

HLA-B\*27 may be a dominant genetic component but the presence of HLA-B\*27 alone is insufficient for the disease to develop. Thus, susceptibility to AS cannot be fully explained by associations with B\*27. GWAS indicate significant associations of non-MHC genes (37–40) including the interleukin-1 gene cluster, interleukin-23 receptor (IL23R) and endoplasmic reticulum-associated aminopeptidase 1 (ARTS1) genes (41–46) with AS. The IL1 gene complex is on chromosome 2 and encodes for IL-1 alpha, IL-1 beta, IL-1 receptor antagonist, and six other genes, IL-1F5 through IL1F10. A meta-analysis (47) confirmed the association of IL-1A with susceptibility to AS. A strong association was seen with three IL-1A SNPs (44). The IL23R is encoded on chromosome 1p31.3 and has been implicated in other diseases such as psoriasis and irritable bowel syndrome (IBD), both of which frequently occur in patients with AS. The IL23R finding strongly implicates the TH17 lymphocyte system in AS pathogenesis. IL17R induces the differentiation of naïve CD4+ T cell into TH17 helper cells. One particular SNP showed a strong association with AS, which was independent of an association with IBD (44,48). ARTS1 is encoded by three genes on chromosome 5. The

two functions of ARTS1 to cleave cytokine receptors (IL-6 receptor A, tumor necrosis factor R1 and IL-1 R2) from the cell surface and to process peptides to an optimal length for presentation by class I molecules (44). Four SNPs in ARTS1 have been found associated with AS. These studies have revealed possible pathways that regulate the disease that may lead to the development of approaches for therapeutic intervention such as targeting the TH17 system.

### 76.7.2 Behcet's Disease (BD)

BD is characterized by recurrent inflammatory attacks affecting the mouth, genital, mucosa, eyes, and skin. BD is prevalent in countries along the ancient silk routes and into Middle Eastern countries. HLA-B\*51 and HLA-A\*26 have been found associated with BD in various ethnic groups including Turkish and Japanese populations (49–51). Studies have also shown an independent MHC class I association telomeric to HLA-B (49). Kurata et al. (52) identified two SNPs in the region from HLA-A to HLA-E that were associated with BD independent of HLA-B\*51 and A\*26. Although HLA-B\*51 appears to be a strong genetic component in BD, it accounts for <20% of the genetic risk, indicating other genetic factors may be involved. GWAS and meta-analysis have identified common variants in IL 10 and at the IL23R-IL12RB2 locus (50,52). Several SNP haplotypes of the IL-10 gene promoter have been reported to be associated with regulation of the gene's expression. Genetic variants contributing to low IL-10 expression resulting in an inflammation-prone state in concert with the presentation of an unknown peptide by the HLA antigens may increase susceptibility to BD.

### 76.7.3 Multiple Sclerosis (MS)

MHC class II and more recently class I associations with MS have been reported as well as non-MHC components. In northern European populations, the RR for HLA-DR2 and MS is modest, on the order of 3. The same DR2 extended haplotype (DRB1\*15:01, DQB1\*06:02, DQA1\*01:02, DRB5\*01:01) (53,54) that confers increased risk for MS is highly protective (see Section 76.7.4) for type 1 diabetes (T1D). In African-American populations, the DRB1\*15:01 has been shown to have an association independent of DQB1\*06:02 (54–56). In Chinese populations, an SNP in an intron of HLA-DPB1 has been shown to have a strong association with MS susceptibility (55,57). Extended haplotype analysis has been handicapped by the very strong linkage disequilibrium across the MHC region. Conditioning studies of an SNP putative independent cluster in the class II and class I regions emerge with HLA-B\*44:02 giving a strong signal (58). A putative role for the class I molecules is to facilitate the transendothelial migration of antigen-specific CD8+ T cells into the brain (59).

Additional disease-associated genes have been discovered through the GWAS including two very interesting genes, protoglycan 5 (GPC5) and PARK2 (Parkin) (60). GPC5 is a member of the glypican family that plays an important role in the control of cell division. Since GPC5 is expressed in neurons, it may be important in interactions with growth factors, chemokines, and other extracellular matrix proteins. PARK2 is a part of the E3 ubiquitin ligase complex that mediated the targeting of substrate proteins for proteasomal degradation. It is abundant in the brain and mutations have been associated with juvenile-onset Parkinsonism (61). Three other SNPs have been found associated with MS along with other autoimmune diseases suggesting that they may play roles in the pathogenesis of different disorders (62).

#### 76.7.4 Type 1 Diabetes (T1D)

For some diseases, there is a hierarchy of risk associated with different alleles and genotypes, rather than a single predisposing allele. For T1D, the RR for the heterozygous genotype DR3/DR4-DQB1\*03:02 is about 30–40, whereas the RR for DR3/DR3 and DR4/DR4-DQB1\*03:02 homozygotes is around 5–8 and DR1/DR4-DQB1\*03:02 and DR4-DQB1\*03:02/DR8 heterozygotes also confer lesser but significant risk. The DR4-associated susceptibility to T1D reflects contributions both from the DQB1 locus, where \*03:02 but not \*03:01 is associated with disease, as well as from the DRB1 locus where \*04:01, \*04:02, and \*04:05 are disease associated. The DRB1\*04:03-DQB1\*03:02 haplotype is negatively associated with T1D. This pattern of disease association, involving specific combinations of HLA alleles, found either in *cis* in haplotypes (i.e. susceptible DRB1 and DQB1 alleles carried on one haplotype) or in *trans* in genotypes (i.e. susceptible allele of DRB1 carried on one haplotype and susceptible allele of DQB1 carried on the other), has been observed in other diseases as well.

Some associations are negative, suggesting a protective role for the associated alleles or haplotypes, such as DR2 and T1D. As noted earlier, the RR for the DR2 haplotype common among whites, DRB1\*15:01-DQB1\*06:02, is around 0.05. Other DR2 haplotypes are not negatively associated with T1D. On the basis of the disease association observed with various DR2 haplotypes (e.g. DRB1\*15:01-DQB1\*04:02 is not protective), the dominant protection conferred by the DRB1\*15:01-DQB1\*06:02 haplotype appears to be attributable primarily to the DQB1\*06:02 allele. It has been noted that this protection may be attributed to the volume of the P6 pocket and the specificity of the P9 pocket of the class I peptide-binding groove (63). DNA-based typing methods have made it possible to evaluate the role of individual polymorphic amino acid residues in HLA disease associations. Comparing a sequence that is disease

associated with closely related sequences that are not, can point to specific polymorphic sequence motifs and, given the known structure, to specific pockets in the peptide-binding groove as functionally important in disease susceptibility or resistance. The role of DQB1 position 57 in T1D susceptibility based on the negative association of Asp-57 with disease is well known (64), but the susceptibility of a given haplotype cannot be predicted by the presence of an individual amino acid residue. Clearly, there are some haplotypes that contain DQB1 Asp-57 (e.g. DRB1\*08:01-DQB1\*04:02 in whites or DRB1\*04:05-DQB1\*04:02 in Asians) that are positively associated with T1D (65).

#### 76.7.5 Pemphigus Vulgaris (PV)

Pemphigus is an autoimmune disease, in which antibodies specific for desmogleins (Dsg3) cause loss of keratinocyte cell adhesion and blisters. The onset and progression of the disease depends on multiple factors including drugs, diet, UV radiation and genetic background. A strong genetics background to PV has been shown in certain ethnic groups, such as Ashkenazi Jews and those of Mediterranean and south Asian origin. Associations between HLA class II alleles and PV have been reported (66–69). HLA-DRB1\*04:02 has been found associated with PV in Jewish populations, whereas HLA-DQB1\*05:03, HLA-DRB1\*14:04 and HLA-DRB1\*14:01 have been found associated in non-Jewish populations (67).

One theory is that this disease is caused by Th2 cells that induce the production of Dsg-specific autoantibodies. It is assumed that the MHC molecule forms a complex with peptides from Dsg3 (70). The negative charge of residues of DR 70 and 71 residues in DRB1\*04:02 and the DQB 57 residue of DQB1\*05:03, for example, confers selective binding to self peptides that have a positive charge at the P4 pocket in the peptide-binding groove. Similarly, the HLA-DRB1\*14:01 allele can present the same Dsg3 peptides. Thus, these alleles are the restricting elements of the T cell response to Dsg3 in PV patients. Antibodies specific for Dsg have been characterized and cloned from patients with PV (71). The variable heavy-chain gene usage complementarity determining region 3 (H-CDR3) was determined to be the most pathogenic. This H-CDR3 is critical in the antibody function and antigen specificity, suggesting that agents interfering with these areas may block pathogenic antibodies.

#### 76.7.6 Narcolepsy

Some autoimmune diseases still show stronger association with HLA than with genes identified by the GWAS. Narcolepsy is a sleep disorder characterized by excessive daytime sleepiness, cataplexy, and rapid eye movement during sleep. Narcolepsy has been shown to be strongly associated with the HLA-DRB1\*15:01-DQB1\*06:02 haplotype (72,73). Almost all Japanese patients with

narcolepsy carry this haplotype compared to only 10% of the general Japanese population. These results suggest that this haplotype alone is not responsible for the development of narcolepsy. The GWAS revealed six genes that were associated with narcolepsy (73). TCRA/DAD1 (T cell receptor- $\alpha$ ) was also identified as a new susceptibility gene in a second study (74). Another gene NFATC2 (nuclear factor of activated T cells, cytoplasmic, calcineurin dependent 2) also shows a significant association with narcolepsy and its expression level is lower in narcoleptic patients. These two genes and HLA all being associated with narcolepsy further support their involvement in the autoimmune disease. Hor et al. (75) found association with a protective variant gene near DQ on the HLA-DQB1\*02-DRB1\*03 haplotype and also on the DRB1\*13:01-DQB1\*06:03 haplotype. More recently the best biological marker for narcolepsy has been found to be a deficiency in the hypothalamic neuropeptide hypocretin-1 leading the hypothesis that narcolepsy is caused by an autoimmune attack targeting hypocretin-producing neurons (76,77). Comparisons between different ethnic groups have indicated that the susceptibility locus is closer to DQB1 locus (75). These findings suggest that HLA class II regions show the strongest association in narcolepsy.

### 76.7.7 Rheumatoid Arthritis (RA)

One of the prominent features of RA is the presence of rheumatoid factor (RF), which is an autoantibody to the Fc portion of IgG and present in most RA patients. Recently, antibodies to citrullinated proteins have been detected in about 80% of RA patients with 98% specificity (78 and references therein). Citrullination is mediated by peptidylarginine deiminases, of which, PADI4 has been identified as an RA-susceptibility gene (79). Citrullinated peptides bind with high affinity to DRB1\*04:01, perhaps explaining some of the HLA association seen with this disease (80). More recently, a variant allele (R620W) of PTPN22, an intracellular tyrosine phosphatase, has been shown to be highly associated with seropositive RA (as well as with T1D and SLE) (81–83).

When patients with citrullinated protein antigen positive forms of RA are studied, the top signal maps to DQA1\*03:01 and the top SMP is located ~2.5 kb upstream from HLA-DRA. Other independent SNP signals are located within the class II region are located between HLA-DQA1 and DQA2; within the HLA-DOB locus, and in the intron of the HLA-DRA locus. Seropositive homozygous patients have an OR equal to 4.57 compared with heterozygotes. No association or interaction with HLA-DRB1 has been seen, suggesting that these are independent susceptibility loci. MICA and MICB have also been implicated in RA. Because they are present on the synovial cells, they can activate autologous T cells through their NKG2D ligand (84).

Specific HLA class II alleles are associated with RA, with risk in white populations increased 5–10-fold for individuals with specific HLA-DRB1\*04 genes, such as DRB1\*04:01 and DRB1\*04:04 and \*04:05. In addition, DRB1\*01 and \*10 also show a weak association in some studies. However, the same alleles are prevalent in the normal population, so that screening for disease susceptibility based on the presence of these alleles is not highly predictive and is not clinically indicated. The absolute risk to an individual positive for one of these specific DR4 susceptibility alleles is, on average, only 8% (range 5–12%), compared with a population prevalence of approximately 1% (85). In addition, there is marked clinical heterogeneity in the spectrum of RA associated with these HLA genes. Although 80–90% of patients with long-standing erosive forms of RA are positive for the DR\*4 susceptibility alleles, only 55–65% of newly diagnosed RA patients carry the same alleles. This observation has been the subject of considerable clinical interest because it appears to indicate that patients diagnosed with RA represent a spectrum of clinical heterogeneity that is caused, in part, by an underlying genetic heterogeneity. Indeed, further studies have shown that the DR4 susceptibility genes are most prevalent in patients with RF and severe erosive RA, and that other class II susceptibility genes, such as DRB1\*01:01, are markers for a broader clinical spectrum that includes seronegative and nonerosive forms of RA (86).

This genetic distinction between severe erosive RA and other forms of polyarthritis has potential clinical utility for prognosis. When individuals newly diagnosed with RA are analyzed, the presence of DRB1\*04 RA susceptibility alleles (e.g. DRB1\*04:01 or \*04:04) predicts progression to severe erosive disease. In studies of patients who met clinical criteria for RA but did not yet have erosive disease (X-ray evidence of joint erosions), the presence of DRB1\*04 susceptibility alleles was correlated with the onset of erosive disease within two years (87–89). Patients who lacked these DR4 susceptibility genes had a high frequency of nonerosive polyarthritis, and a low frequency of erosive and progressive RA. In other studies using unselected RA patients, there was little additional prognostic value shown for use of these genetic tests in patients who already had erosive disease, indicating that the positive predictive value of DRB1\*04 analysis is probably limited to use in early patients, who do not yet have severe disease (90).

Therefore, although the association between HLA-DR genes and RA suggests a role for HLA molecules in disease susceptibility, the current practical clinical utility lies in the association between specific RA susceptibility alleles and prognosis for progressive erosive forms of disease. HLA-DRB1\*04 genetic analysis is potentially useful in this regard as a means to select patients for alternative forms of therapy. In a randomized clinical trial comparing an aggressive form of multidrug therapy for RA with a single-drug regimen,

there was a marked distinction in clinical outcome that corresponded to the HLA-DRB1\*04 genetic analysis (91). The DRB1\*04-negative patients, as expected, had overall milder disease course over the 2-year clinical trial, and they responded well to both arms of the clinical trial. Patients treated with the single-drug regimen responded to therapy with an excellent clinical outcome (83% response). In contrast, the DRB1\*04-positive patients who were randomized to the single-drug regimen did very poorly, with a marginal (32%) clinical response. The DRB1\*04-positive patients who received the multidrug treatment, however, had a 94% response rate, comparable to the DR4-negative groups (88%). Thus, the use of HLA-DR4 genetic typing to influence the selection of “aggressive” vs standard therapies in RA for newly diagnosed Caucasoid patients who do not yet have joint erosions may be a valuable adjunct to medical management in this disease.

### 76.7.8 Risk Estimates

As noted earlier, a variety of diseases has been associated with specific HLA class I or class II alleles. Risk estimates for the disease-associated marker can be calculated based on the distribution of the marker in patients and controls. The mathematical definitions of various parameters used to estimate genetic risk are shown in Table 76-3 (92). The odds ratio (or RR) gives the probability that someone with the specific marker will get a given disease relative to someone without the marker. The absolute risk refers to the probability that someone with the marker will get the disease; this estimate is related to the disease incidence. The etiologic fraction (or population attributable risk) is yet another risk parameter, measuring what

proportion of the disease risk can be attributed to this gene.

Studies of multiplex families or of affected sib pairs also allow one to estimate the proportion of the total genetic risk attributable to a given genetic region defined by a specific marker; this approach involves calculating a value ( $\lambda_s$ ) from the ratio of expected to observed affected sib pairs that share zero haplotypes (93). For insulin-dependent diabetes mellitus (IDDM), for example, the observed proportion of affected sib pairs sharing zero HLA haplotypes is about 0.06; the expected proportion is 0.25, yielding a  $\lambda_s$  for HLA of about 4.1. For IDDM, the familial clustering or sibling risk ratio (total  $s$ ), the ratio of sibling risk to population prevalence is about 15. This familial clustering ratio may include components of both genetic risk and shared environmental factors. A value of about 50% for the proportion of familial clustering attributable to the HLA region (95) can be calculated, making certain assumptions, from these estimates of  $s$ . By comparison, the value of  $s$  for seropositive, erosive RA is between 5 and 10, whereas for SLE or MS, it is about 20 (94).

### 76.7.9 The Role of Non-HLA Genes within the MHC in Disease

A large number of non-HLA genes within or near the MHC appear to be responsible for several presumed HLA-associated diseases. Some of these diseases have no obvious immunopathology. For example, hereditary hemochromatosis, an autosomal-recessive disease of excessive iron storage associated with HLA-A3, is now known to result from a mutation in the HFE locus. HFE is a class-I-like gene telomeric to the MHC that is involved in iron transport (96). Its product normally associates with beta-2 microglobulin, but a common HFE polymorphism can abrogate its ability to bind, thereby making the molecule nonfunctional (33). There are also several non-HLA genes within the MHC that have an immunologic function that have been implicated in disease susceptibility. Polymorphisms in the promoter of the TNF-alpha locus have been associated with several autoimmune as well as infectious diseases (97,98). These polymorphisms are thought to affect the level of TNF-alpha produced in response to certain stimuli. A second RA-susceptibility locus, located within the MHC, is found in I kappa BL. A single nucleotide polymorphism (SNP 96452 T/A) in the promoter region disrupts a putative binding motif for the transcriptional repressor delta EF1 and may influence transcription of I kappa BL (99). Null alleles at the C4 locus (a component in the complement cascade) appear to contribute to several diseases, including SLE. As noted earlier, it is likely that the well-known association of SLE with the B8-DR3 haplotype is due to strong linkage disequilibrium with the C4A null allele.

The role of the recently identified MICA and MICB (for MHC class-I-associated chain) loci, located about

**TABLE 76-3** Definition of Risk Estimates

		Marker	
		+	–
Disease	0	<i>a</i>	<i>b</i>
	–	<i>c</i>	<i>d</i>

*a* = number of patients with marker.

*b* = number of patients without marker.

*c* = number of controls with marker.

*d* = number of controls without marker.

$$\text{Odds ratio (relative risk)}^a = \frac{ad}{cb}$$

$$\text{Absolute risk} = \frac{a/(a+b)}{c/(c+d)} \times \text{disease incidence.}$$

$$\text{Etiologic fraction} = \frac{[a/(a+b) - c/(c+d)]}{1 - [c/(c+d)]} \text{ (population attributable risk).}$$

<sup>a</sup>The relative risk used by epidemiologists for prospective studies differs slightly from the odds ratio used in case-control studies and is defined as  $a(ac)/b(bd)$ . For rare diseases in which *a* and *b* are small relative to *c* and *d*, this expression approximates the odds ratio.

45kB centromeric of HLA-B, in disease susceptibility is still unclear. There are 76 alleles at MICA and 31 alleles at MICB (<http://hla.alleles.org/classo.html>, April 2011). These genes encode class-I-like glycoproteins that serve as ligands/restriction elements for the TCR of gamma-delta T cells but certainly also function as ligands for the NKG2D-activating receptor on NK cells. These receptors on NK cells can either activate NK cells directly or act as costimulatory molecules for T-cell activation independent of the TCR. It has been suggested that certain alleles of MICA and/or MICB may predispose to certain HLA-associated diseases, such as Behçet's disease or to CD. This latter disease is an interesting candidate because it appears to involve the action of gamma-delta T cells in the gut. However, the issue of linkage disequilibrium with disease-associated B locus alleles (e.g. B\*51) in the case of Behçet's disease, or DR-DQ haplotypes (e.g. DRB1\*03-DQB1\*02) in the case of CD, will have to be examined carefully to assess the true role of polymorphism at these loci in disease susceptibility.

#### 76.7.10 The Role of NK Cell Receptor Genes in Autoimmune Disease

Autoimmune disease has also been associated with the KIR/NKG2/CD94 genes, which are receptors found on NK cells whose ligands are HLA glycoproteins or other class-I-like molecules. Activating killer cell immunoglobulin-like receptor (KIR), especially KIR2DS1 and KIR2DS2, has been implicated in autoimmune disease such as RA and psoriatic arthritis (PsA) (100). Because the affinity of the HLA-C group ligand binding is higher for the inhibitory KIR2DL1 and KIR2DL2/3 receptors than it is for the activating KIR2DS1 and KIR2DS2 receptors, disease appears to ensue when the balance is disrupted. For PsA, it appears that disease susceptibility is a function of the sum total of the activating and inhibitory KIR-ligand combinations that are present, where genotypes corresponding with strong activating potential increase the risk of developing disease. Thus, the particular array of KIR or KIRs present on any given cell will dictate the response of that cell, and the sum total of the population of cells will dictate the susceptibility to PsA.

#### 76.7.11 The Role of Non-MHC Disease Genes

Although the HLA loci and, possibly, other genes within the MHC play a critical role in many autoimmune and inflammatory diseases, other genes also contribute significantly to disease risk. Linkage studies using segregation analyses (parametric) and haplotype sharing among affected sib pairs (nonparametric) have been carried out for a variety of diseases, notably T1D MS, RA, and inflammatory bowel disease, using genome-wide scans with microsatellite markers and haplotype maps (18,94,101–104). These studies have identified several

regions of significant linkage, including the MHC, for all of these diseases, although not all studies for the same disease have implicated the same chromosomal locations (105). In general, the genes responsible for the observed disease linkage to a chromosomal region have not yet been identified and extensive association studies with candidate genes and anonymous genetic markers mapping in these regions are under way in many labs. For example, many associations and some linkage studies carried out in several populations suggest that the insulin locus (chromosome 11p15) and the CTLA4 locus (chromosome 2q33) are involved in susceptibility to T1D. Polymorphism in the CTLA4 locus has been associated with other autoimmune diseases as well (106). The functional polymorphism (R620W) in the PTPN22 gene that encodes the lymphoid protein tyrosine phosphatase (LYP) has been shown to be associated with a variety of autoimmune diseases such as T1D (6), RA, and SLE (81,94). Unlike the variant encoded by the more common allele (R620), the LYP variant (W620) associated with autoimmunity does not bind the negative regulatory kinase, Csk.

#### 76.7.12 Celiac Disease (CD): An Instructive Example

CD is an inflammatory autoimmune disease of the intestinal mucosa, elicited by ingestion of wheat gluten or gliadin. In terms of elucidating immunologic mechanisms, CD is one of the most informative of the HLA-associated diseases because the pathogenic antigen is known and antigen-specific T cells can be recovered from the gut and analyzed *in vitro*. In terms of identifying the molecule responsible for the observed disease association with the DRB1\*03:01-DQA1\*05:01-DQB1\*02:01 and DRB1\*07:01-DQA1\*02:01-DQB1\*02:01 haplotypes, the genetic association studies on CD have also been instructive. The strongest associations with CD are with the *cis* DRB1\*03 haplotype (DRB1\*03:01-DQA1\*05:01-DQB1\*02:01) and with the *trans* genotype DRB1\*11/DRB1\*07 (DRB1\*11-DQA1\*05:01-DQB1\*03:01/DRB1\*07:01-DQA1\*02:01-DQB1\*02:01). A unifying interpretation of this association pattern is that the molecule responsible for the disease association is the DQ heterodimeric molecule with the alpha chain encoded by DQA1\*05:01 and the beta chain encoded by DQB1\*02:01 (106,107). This molecule is encoded in *cis* by the DRB1\*03 haplotype and is formed as a trans-complementing heterodimer in a DRB1\*011/DRB1\*07 heterozygote. This model represents strong evidence that the HLA polymorphism associated with CD is not simply a genetic marker in linkage disequilibrium with some other disease gene but is causally related to disease susceptibility.

T cells have been isolated from the gut of CD patients that recognize specific peptides in the context of the DQ2 molecule. The sequence analysis of peptides bound to the

molecule encoded by DQA1\*05:01 and DQB1\*02:01 has been determined, and the binding motif has been identified (109). Surprisingly, this motif, which contains glutamic acid, is not found in gliadin and other components of wheat gluten. The resolution to this apparent paradox was the discovery of an enzyme, tissue transglutaminase, present in the gut. This enzyme converts glutamine to glutamic acid in gliadin, creating peptides that are then capable of being bound by the DQ2 molecule and presented to T cells. Increased levels of tissue transglutaminase have been observed in the jejunal biopsies of patients and antibodies to this enzyme are a hallmark of CD (110). Thus, the genetics of CD can be best explained by preferential binding and presentation of a modified gliadin peptide by the DQ molecule encoded by the disease-associated alleles DQA\*05:01 and DQB1\*02:01. The demonstration of the role of this DQ molecule in CD does not mean, however, that other genes within and outside the MHC do not also contribute to genetic susceptibility for this disease. As noted earlier, multiple genes, as well as environmental factors, are likely to be involved in all of the many diseases associated with specific HLA alleles.

### Biographies

**Dr Nancy L Reinsmoen** received her BA from Luther College, Decorah, Iowa and MS and PhD in Pathobiology and Immunogenetics from the University of Minnesota, Minneapolis, MN. During her 26 years at the University of Minnesota, she held positions as Senior Scientist in the Cellular Histocompatibility Laboratory and Director of the Transplant Immunology Laboratory in the Department of Surgery, where she also held academic appointments of Assistant Professor and Associate Professor. Subsequently, she was appointed as Director of the Clinical Transplantation Immunology at Duke University, Durham, NC and was a tenured full Professor in the Department of Pathology. Dr Reinsmoen's current position is Director of the HLA and Immunogenetics Laboratory at Cedars-Sinai Medical Center, Los Angeles, CA and Professor of Pediatrics, David Geffen School of Medicine, University of California, Los Angeles. Dr Reinsmoen has held several national positions including President of the American Society for Histocompatibility and Immunogenetics (ASHI) and member of Board of Directors for the United Network for Organ Sharing (UNOS). Currently, she is Chair of the Histocompatibility Committee for UNOS. She has received several awards including, most recently, the ASHI Distinguished Scientist Award. She has authored over 190 original manuscripts, chapters, and invited review papers.

**Dr Kai Cao** received both her MD and MS in dermatology and immunogenetics from China Medical University, Shenyang, China. She had 1-year scholarship in the Laboratory of Immunogenetics at the National Cancer Research Institute in Genoa, Italy. Then, she has worked in the National Histocompatibility Laboratory of the American Red Cross and the Histocompatibility Laboratory at the University of Maryland Medical System for 8 years, where she held positions as Senior Scientist and Supervisor. Subsequently she worked at the C.W. Bill Young/Department of Defense Marrow Donor Program at the Naval Medical Research Center and Georgetown University School of medicine, where she held positions as laboratory Supervisor and General Supervisor. Dr Cao's current position is Associate Director at the HLA laboratory of Cedars-Sinai Medical Center in Los Angeles, CA. She has been a member of the American Society of Histocompatibility and Immunogenetics (ASHI), the International Society for Heart and Lung Transplantation (ISHLT) and the American Society of Transplantation (AST). During her 20 years working in the field of Histocompatibility and Immunogenetics, Dr Cao has discovered numerous new HLA gene sequences which were registered in the International ImMunoGeneTics Project (IMGT) database and has authorized over 40 original manuscripts and chapters.

**Dr Lai** graduated from Soochow University, Taipei, Taiwan in 1984 with a bachelor's degree in Chemistry. He completed his Master of Science degree in Clinical Science, Bioanalysis option in 1995 at California State University, Dominguez Hills. In 2004, he earned his doctoral degree from University of California, Los Angeles, Department of Pathology and Laboratory Medicine. Dr Lai completed his Clinical Molecular Genetics fellowship at the University of California, Los Angeles in 2007. He did his Histocompatibility and Immunogenetics director training at Cedars-Sinai Medical Center, Los Angeles, CA, 2007–2011. Dr Lai is board certified in Histocompatibility and Immunogenetics.

Dr Lai is a Diplomat of the American Board of Histocompatibility and Immunogenetics and is an active member of many professional societies. Dr Lai serves on the committee of American Society for Histocompatibility and Immunogenetics. In addition, he is an Inspector for American Society for Histocompatibility and College of American Pathologists. He has more than 15 peer reviewed articles on variety of subjects such as virology, genetics and histocompatibility. Dr Lai is currently a Clinical Associate PhD in the HLA and Immunogenetics Laboratory at Cedars-Sinai Medical Center.

# Systemic Lupus Erythematosus

*Yun Deng, Bevra H Hahn and Betty P Tsao*

Department of Medicine, David Geffen School of Medicine, University of California,  
Los Angeles, CA, USA

This article is a revision of the previous edition article by Betty P Tsao and Bevra Hannahs Hahn, volume 2, pp 1777–1792,  
© 2007, Elsevier Ltd.

## 77.1 INTRODUCTION

Systemic lupus erythematosus (SLE) is a prototype autoimmune disease characterized by autoantibody production, immune complex deposition, and heterogeneous clinical manifestations. Epidemiologic studies on the sibling risk ratio, familial aggregation of SLE and the disease concordance rate in monozygotic twins support a strong genetic contribution to the development of SLE (1). The inheritance of SLE is complex, following a polygenic model that common variations in a number of genes are involved, each contributing modestly to disease risk (2). As a genetically complex disease, SLE typically exhibits genetic heterogeneity, which has been demonstrated by genetic association analyses stratified by specific clinical features and ethnic backgrounds. In addition, *epistasis*, that is, interactions between genes or between genes and environmental factors, should be considered as potentially important determinants of disease risk.

Numerous genetic studies on SLE have been performed. Before 2007, the main approaches to explore genes predisposing to disease risk are (1) targeted and genome-wide linkage studies using multiplex families and (2) candidate gene association studies, usually performed using unrelated cases and ethnically matched control individuals. In the past four years (2007–2011), genome-wide association (GWA) studies that represent an important step beyond the two aforementioned methods have revolutionized the search for genetic influences on SLE susceptibility with more than 30 disease-associated loci identified and confirmed in large datasets. Efforts in delineating functional variants underlying SLE-associated signals and rare variants that may have strong impact in risks for SLE are underway. Results from these studies will help elucidate the molecular mechanisms and cellular pathways modulated by robust genetic associations with SLE, and should provide new targets for more focused therapies.

## 77.2 HISTORICAL BACKGROUND, DEFINITION, AND CLASSIFICATION

The milestones in the history of SLE have been reviewed. The term *lupus*, meaning wolf in Latin, was used in medieval times to describe erythemic ulcerations that can eat away the face. The ability of lupus to cause multisystem disease was described approximately 130 years ago. During the past 30 years (1980–2011), clinical and laboratory definitions of this disease have been characterized and refined. A set of classification criteria for SLE was developed and revised by the American Rheumatism Association (now the American College of Rheumatology) exhibiting 96% sensitivity and 96% specificity (3). Subsequently, the 11 classification criteria for SLE were updated as shown in Table 77-1 (4). Individuals who fulfill four or more of 11 criteria are classified as SLE patients. The criteria were designed for classification of the disease in studies involving SLE patients rather than as a diagnostic tool for individual patients.

## 77.3 PATHOGENIC AUTOANTIBODIES AND IMMUNE COMPLEXES

The wide array of clinical features observed in SLE patients is often mediated by pathogenic autoantibodies and their immune complexes. Autoantibodies may start appearing in symptom-free individuals by years before the diagnosis of SLE, followed by a gradual acquisition of more autoantibodies and clinical symptoms (5). SLE patients usually have high-affinity immunoglobulin G (IgG) autoantibodies to self-antigens, which are different from normal individuals who have a repertoire of IgM autoantibodies displaying low affinity to a multitude of antigens, including self-antigens. Characteristics of autoantibodies present in SLE patients often resemble protective IgG antibodies induced in immune responses against foreign antigens. These autoantibodies have been shown to be the products of clonally expanded B cells, which

**TABLE 77-1 1997 Revised American College of Rheumatology Criteria for SLE Classification<sup>a</sup>**

Criterion	Definition
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds.
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging, atrophic scarring may occur in older lesions.
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation.
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician.
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling or effusion.
6. Serositis	(a) Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion; OR (b) Pericarditis—documented by ECG or rub or evidence of pericardial effusion.
7. Renal disorder	(a) Persistent proteinuria >0.5 g per day or >3+ if quantitation not performed; OR (b) Cellular casts—may be red cell, hemoglobin, granular, tubular, or mixed.
8. Neurologic disorder	(a) Seizures—in the absence of offending drugs or known metabolic derangements (e.g. uremia, ketoacidosis, or electrolyte imbalance); OR (b) Psychosis—in the absence of offending drugs or known metabolic derangements (e.g. uremia, ketoacidosis, or electrolyte imbalance).
9. Hematologic disorder	(a) Hemolytic anemia—with reticulocytosis; OR (b) Leukopenia—<4000/mm <sup>3</sup> total on two or more occasions; OR (c) Lymphopenia—<1500/mm <sup>3</sup> on two or more occasions; OR (d) Thrombocytopenia—<100,000/mm <sup>3</sup> in the absence of offending drugs.
10. Immunologic disorder	(a) Anti-DNA: antibody to native DNA in abnormal titer; OR (b) Anti-Sm: presence of antibody to Sm nuclear antigen; OR (c) Positive finding of antiphospholipid antibodies based on: (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies; (2) a positive test result for lupus anticoagulant using a standard method; or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test.
11. Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with “drug-induced lupus” syndrome.

<sup>a</sup>The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have SLE if any four or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

are descendants of the initial antigen-activated B cells. In addition, these autoantibodies often have somatic mutations in the variable regions of their immunoglobulin genes that enhance the binding affinity for their selected autoantigens. The constant regions of these autoantibodies also play a role in disease. Those autoantibodies with isotypes that fix complement well are more likely to be pathogenic. The production of different autoantibodies appears to correlate with heterogeneous clinical manifestations of lupus. For example, elevated serum IgG antibodies to double-stranded DNA (dsDNA) are associated with immune-complex-mediated glomerulonephritis (6), antibodies to phospholipid with thrombosis and recurrent fetal loss (7), and antibodies to ribonucleoprotein (Ro) with photosensitive skin rash and congenital heart block (7,8).

Many autoantibodies associated with SLE recognize altered autoantigens displayed on the membranes of cells undergoing apoptosis, leading to the current thinking that these autoantibodies are induced by increased rates of apoptosis, and/or abnormal clearing of apoptotic cells (9,10). As apoptosis occurs in normal physiologic conditions to maintain tissue homeostasis, the loss of tolerance to autoantigens in apoptotic blebs (such as nucleosome, phospholipid, and Ro) may reflect defects in immunoregulation of apoptosis resulting in survival of autoreactive B and T lymphocytes. Environmental insults such as ultraviolet (UV) light can induce apoptosis of keratinocytes, leading to redistribution of several autoantigens to the

surface of cells in membrane-encased blebs. These redistributed autoantigens, including DNA/histone complexes (nucleosomes or chromatin), Ro particles, and phosphatidylserine (the negatively charged inner-membrane component), are normally sequestered from the immune system, but become available when presented on cell surfaces during apoptosis. In addition, these autoantigens may be altered by processes occurring during apoptosis that make them more immunogenic, thus inducing autoantibody production, as shown in normal mice following systemic exposure to irradiated apoptotic cells (11). Defective clearance of apoptotic cells in individuals with a single gene deficiency in classical complement components (C1q or C4) can cause lupus-like disease in normal mice (12,13), and almost all humans with homozygous C1q deficiency develop lupus (14).

## 77.4 THE GENETICS OF HUMAN SLE

### 77.4.1 Genome-Wide Linkage Studies

Several different study designs that involve sibling pairs (for whom, parents may or may not be available) or extended pedigrees with several generations have been used for linkage scans to explore susceptibility loci for SLE. A total of 12 genome-wide scans and 8 targeted linkage analyses have established nine loci (1q23, 1q31–32, 1q41–43, 2q37, 4p16, 6p11–21, 10q22–23, 12q24, and 16q12–13) reaching the threshold for significant

linkage to SLE (15), which have also been replicated in independent populations (16–28). Confirmation of significant linkage of a locus offers strong evidence for the existence of putative susceptibility gene(s), which leads to further narrowing of the linked loci to localize susceptibility genes. These promising linkage loci and the susceptibility gene(s) identified within these regions are summarized in Table 77-2.

**77.4.1.1 Linkage Analysis Using Pedigree Stratification Approach.** The extremely diverse and variable clinical manifestations of SLE both in individual patients and over time have promoted a hypothesis that genetic factors contribute to this disease heterogeneity. There is likely to be a set of genes which are overrepresented in families with particular clinical manifestations. Stratification of multiplex pedigrees by clinical symptoms is a rational approach to increase power for detecting linkage if phenotypic heterogeneity is affected by genetic heterogeneity (29). This approach has been applied successfully in the Oklahoma collection, which has yielded 10 publications reporting strong evidence for linkage (Table 77-3) (30–39). However, reduced sample size after phenotype stratification and the high probability of false-positive results from repeatedly testing subgroups highlight the importance of independent confirmation of the findings. Rather than stratifying on the presence or absence of a single manifestation, a principal component approach using seven major SLE-related phenotypes plus age at SLE onset and race was used to conduct multivariate analysis of the genome scan data. This approach has identified several loci exhibiting suggestive evidence for linkage to SLE-related traits (40). Familiality of thrombocytopenia, discoid rash, neurologic disorder (defined as seizure or psychosis), hemolytic anemia, co-occurring neurologic disorder plus hemolytic anemia and age at SLE diagnosis have been observed in 159 sibling pairs affected with SLE (41). Linkage to familial subphenotypes of SLE may improve homogeneity and facilitate the localization of susceptibility genes predisposing to particular clinical manifestations.

**77.4.1.2 Meta-analysis of Genome-Wide Scans.** Although a number of genomic regions harboring SLE susceptibility genes have been established in individual

genome-wide scans, many other regions have yielded inconsistent results across studies. Additionally, studies from a single center may be limited with regard to the acceptable power recommended for declaring significant linkage. Thus, the genome scan meta-analysis method, which is designed to deal with variation in study designs, analysis methods and marker densities used in different single center scans, has been proposed as a valid and robust tool for combining numerous linkage results (42). The two genome meta-analyses have reported several linked regions that may harbor SLE susceptibility genes, including three linkage intervals (6p21–6p22, 16p12–16q13 and 20p11–20q13) that appeared in both analyses. Some regions (such as 3p14–3q12, 10p14–10q11 and 12q24–12qter) appeared only in one analysis (43,44). Some of loci linked to SLE and/or SLE subphenotypes have been validated in subsequent fine-mapping studies leading to the identification of robust disease-associated loci; for example, *ITGAM* in 16p12–16q13, and *PDHX/CD44* in 11p13 as described below.

**77.4.1.3 Recent GWAS Findings Related to Linkage Results.** Success in the initial identification of chromosomal regions containing SLE susceptibility genes was achieved through linkage studies, but the utility of linkage studies in precisely localizing causal variants is limited owing to the inability to map genetic variants of small phenotypic effect sizes. Recently, GWAS technologies that allow efficient and high-throughput genotyping for single nuclear polymorphisms (SNPs) have enabled genome searches for variants predisposing to SLE.

**77.4.1.3.1 6p21 and HLA Genes.** Before the advent of GWAS, one of the most extensively studied regions linked to SLE susceptibility was human leukocyte antigen (HLA), which is encoded by the major histocompatibility complex (MHC) locus. The classical MHC encompasses approximately 3.6 Mb on 6p21.3 and is divided into the class I, class II and class III regions (reviewed in Chapter 76). Given that long-range linkage disequilibrium (LD) and MHC-related genes exist outside this classically defined locus, the concept of the extended MHC (xMHC) spanning nearly 7.6 Mb of the genome has been established. It consists of five subregions: the extended class I subregion (*HIST1H2AA-MOG*; 3.9 Mb), classical class I (*C6orf40-MICB*; 1.9 Mb), classical class III (*PP1P9-NOTCH4*; 0.7 Mb), classical class II (*C6orf10-HCG24*; 0.9 Mb), and the extended class II subregions (*COL11A2-RPL12P1*; 0.2 Mb) (45). Of the 421 genes within this extended region, 60% are expressed and approximately 22% have putative immunological function.

Until 2005, most published disease association studies of HLA were restricted to a subset of ~20 genes in small case-control panels of predominant European ancestries. These genes include the classical HLA loci (*HLA-A*, *-B*, *-C*, *-DRB*, *-DQA*, *-DQB*, *-DPA*, *-DPB*), *TNFA*, *LTA*, *LTB*, *TAP*, *MICA*, *MICB* and the complement loci (*C2*, *C4A*, *C4B* and *CFB*) (reviewed in Fernando and Vyse (46)). A recent pooled analysis which was undertaken to consolidate and evaluate the current literature base regarding HLA genetics with SLE over the past 30 years (1970–2008) has highlighted the importance of variants within *HLA-DR3*- and *HLA-DR2*-bearing haplotypes in SLE susceptibility (47). The strongest associations are found with the *HLA-DR3* haplotypes, *HLA-B8-DRB1\*0301* and *HLA B18-DRB1\*0301* [odds ratio (OR): 1.5–2.5]; the *HLA-DR2/DRB1\*1501* haplotype exhibits OR of 1.7. The remaining association signals largely arise from class II alleles *HLA-DRB1*, *HLA-DQA1* and *HLA-DQB1*, some of which exhibit evidence of population specificity (47). For instance, *HLA-DRB1\*1503* (a *HLA-DR2* subtype) has been found in African-Americans only although there are several studies in African-Americans revealing no association of *DR2* or *DR3* alleles with SLE susceptibility (48,49). *HLA-DRB1\*1602* has been observed in Mexican Mestizo, Thai, and Bulgarian populations; while *HLA-DRB1\*0401* has been seen largely in Mexican Mestizo and Hispanic populations (47).

Two further class II alleles, *HLA-DQA1\*0401* and *HLA-DQB1\*0402*, reside on a *DR8* haplotype, which is uncommon in European populations (47). These studies have shown inconsistent results, but may help elucidate the risk factors for SLE within the HLA region among multiple populations.

There is strong and complicated LD between genetic markers across the HLA region; thus, highly correlated variants spanning multiple genes are inherited together in a single block. Intense efforts are underway to dissect the independent effects of tightly linked loci. The increased knowledge of the human genome structure and technological advances in the efficient high-throughput genotyping have led to the availability of dense marker sets across HLA locus. Together with collaborative efforts allowing the analysis of several thousands of individuals, these marker sets have enabled extensive fine mapping of HLA variants associated with SLE. Recent GWAS in populations of European and Asian ancestries have shown consistent evidence that the strongest contribution to risk for SLE susceptibility resides in the HLA region and consists of multiple genetic effects (50–55). Of interest, these studies not only confirmed predominant association signals at the class II region, but also highlighted the importance of class III genes in SLE susceptibility. For example, one SNP (rs3131379) of the HLA class III locus *MSH5* exhibited the highest association in a GWAS conducted in 2008 (51). Using a relatively high-density SNP map of HLA, data from several studies in SLE patients has refined these associations (56,57). A mapping study in 314 European SLE families reported two distinct and independent signals (56): one from a small 180-kb class II region tagged by *HLA-DRB1\*0301* allele; and the other observed at an SNP marker (rs419788) in the class III gene *SKIV2L* [superkiller viralicidic activity 2-like (*Saccharomyces cerevisiae*)]. Examination of LD structure around this marker (rs419788) showed that this class III signal could also be limited to a 40-kb interval containing the genes *CFB* (complement factor B), *RDBP* (RD RNA binding protein), *DOM3Z* [dom-3 homolog Z (*Caenorhabditis elegans*)] and *STK19* (serine-threonine kinase 19). *CFB* encodes complement factor B, which is a vital component of the alternate complement pathway (58). The functions of *RDBP*, *SKIV2L*, *DOM3Z* and *STK19* are not well characterized although their products have been reported to play a role in mRNA processing (59). Moreover, transcripts of *RDBP* and *SKIV2L*, in particular, are detectable in T, B lymphocytes and dendritic cells (56). It is notable that this study shows evidence against an independent effect from *TNF-308G/A* promoter polymorphism in SLE, which is inconsistent with results from another meta-analysis study (60). A recent collaborative study has demonstrated HLA associations in multiple immune-mediated diseases, exhibiting complex and multilocus effects (57). In the SLE cohort of European ancestry, the most highly associated SNP (rs1269852) is

detected at class III region between *TNXB* and *CREBL1* genes, which has strong but not complete LD with the *HLA-DRB1\*0301* allele ( $r^2=0.78$ ). Other class III association signals include peaks centered around the *NOTCH4* gene and those on either side of the *RCCX* module (which contains *C4A* and *C4B* genes along with three neighboring genes). The influence of copy number variation (CNV) at the complement *C4/RCCX* locus in relation to the association signals revealed in this study remains to be established (57).

Despite the fact that association of the HLA region with SLE susceptibility has been well confirmed using GWAS and high-density SNP studies, there appear to be limitations such as the inability of these studies to capture CNV and/or to pinpoint the causal gene variants within this complicated region. Alternative methods, including comparative genomic hybridization array and multiplex ligation-dependent probe amplification, are therefore being employed to more accurately assess the effect of the structural variation in disease susceptibility. Next-generation sequencing of associated intervals/haplotypes in large transethnic cohorts will contribute greatly to further refine the HLA association signals in SLE.

**77.4.1.3.2 16p12–16q12 and *ITGAM*.** The product of *ITGAM* is integrin  $\alpha M$  which combines with integrin  $\beta_2$  to form a leukocyte-specific integrin. The  $\alpha M\beta_2$  integrin regulates leukocyte adhesion and emigration through interactions with a myriad of ligands that are potentially relevant to SLE (such as ICAM-1, ICAM-2, C3bi and fibrinogen) (61). The expression level of  $\alpha M\beta_2$  integrin is elevated in neutrophils from SLE patients with active disease activity, which correlates to endothelial injury (62). Other functions of  $\alpha M\beta_2$  integrin involved in autoimmunity processes are its importance in clearing immune complexes and in suppressing Th17 cell differentiation (63,64). Two independent GWAS performed in European populations have reported four SNPs associated with SLE in or very near the gene encoding integrin  $\alpha M$  (*ITGAM*, or *CD11b*) (50,51), which is located within the previously identified linkage interval of 16p12.3–16q12.2. Consistent with these results, a fine-mapping study showed that a nonsynonymous variant (rs1143679; R77H), with an effect on structural and functional changes of integrin  $\alpha M$ , contributed to SLE susceptibility (65). In a subsequent meta-analysis, this association and the role of rs1143679 were confirmed in various ethnicities, including Americans of European, Hispanic or African ancestries, as well as Mexican and Colombian populations (66). Despite the low frequency of the risk allele in Asian populations, it also displayed significant associations with SLE risk as well as with severe manifestations (such as lupus nephritis, neurological, hematological and immunological disorders) in Hong Kong Chinese and Thai individuals (67). However, the correlation of this variant with different clinical manifestations will need further replication using enlarged samples.

**77.4.1.3.3 11p13 between *PDHX* and *CD44*.** Initial GWAS in SLE have not only identified several novel susceptibility loci, but also generated a number of candidate loci not reaching genome-wide significance ( $p < 5 \times 10^{-8}$ ). For example, putative association at 11p13 from an European SLE GWAS (52) has been confirmed in a recent replication study using >15,000 multiethnic case-control samples (68). One intergenic SNP rs2732552 displays robust association with SLE in European, African-American and Asian populations, while another intergenic SNP rs387619 only has association in a European population (68). This region that has also been identified in a linkage study of multiplex SLE families with thrombocytopenia (36) lies between two immune-related genes *PDHX* and *CD44*. *CD44* encodes a cell-surface glycoprotein expressed on most immune cell types that plays an important role in lymphocyte activation, recirculation, apoptosis, hematopoiesis and tumor metastasis (69,70). Although no direct evidence shows SNPs within the *CD44* gene are associated with SLE susceptibility (68,71), there are several reports regarding levels of alternative spliced mRNA transcripts and CD44 protein related to the disease, supporting a role for *CD44* involved in SLE pathogenesis. Li et al. has reported that T cells from SLE patients display elevated levels of CD44 and enhanced adhesion and chemotactic migration compared with T cells from normal individuals or RA patients (72). CD44 is also highly expressed in T cells infiltrating in the kidneys of patients with lupus nephritis when compared to patients with renal allografts undergoing rejection (72). Additionally, a recent study has demonstrated that T cells from SLE patients overexpress CD44v3 and CD44v6 transcript isoforms, and the expression levels are correlated with disease activity (73).

## 77.4.2 Candidate Gene and GWAS

Linkage studies have been successful in identifying chromosome regions linked to SLE, but progress toward further localizations of underlying gene variants has met with limited success. The identified linkage intervals are usually large and contain many potential candidate genes, while in some instances, important SLE susceptibility genes (such as *IRF5*, IFN regulatory factor 5) are not located within established linkage regions. Major advances in gene discovery are summarized here, highlighting the success of both insightful candidate gene approaches and recent GWAS.

**77.4.2.1 Candidate Gene Studies in SLE.** Candidate gene studies are commonly used to assess whether a test genetic marker is present at a higher frequency among patients with SLE than in ethnically matched healthy control individuals. Some candidate genes are chosen based on data from linkage studies, and others on the basis of their functional relevance to the disease pathogenesis. In the majority of cases, the genetic marker under investigation is the SNPs. An SNP observed with

greater-than-expected frequency in individuals with disease is either a functional, disease-causing variant (a direct association) or a nonfunctional variant that exhibits strong LD with the functional variant (an indirect association) (74). Many loci have been implicated in risk for SLE over the years 1981–2010 (reviewed in Tsao & Deng (75)). However, owing to the variations in sample size, ethnicity and number of SNPs studied among individual reports, conflicting results often appear which lead to a limited number of confirmed SLE susceptibility genes. This situation changed dramatically with the advent of GWA studies.

**77.4.2.2 Overview of GWA Studies in SLE.** Since 2007, six GWAS and a series of subsequent targeted replication studies in SLE have been published (50–55,76), which have expanded the number of established genetic associations with SLE to more than 30 (Table 77-4). Such associations are consistent with the common disease–common variant (CD/CV) hypothesis, which assumes that genetic variants present in more than 1–5% of the population confer an important contribution to common diseases (77). The identified SLE-associated variants each have a modest magnitude of risk with an OR in the range of 1.1–2.3 (Table 77-4), accounting for a fraction of the overall genetic risk for SLE. However, they indicate that many different pathways, processes and cell types are involved in generating the SLE phenotype (Figure 77-1), refining our understanding of SLE pathophysiology to the molecular level. Most of these susceptibility loci can be assigned into three key biological pathways: (1) clearance and processing of immune complex; (2) Toll-like receptor (TLR)/type I interferon (IFN) signaling in innate immune response; and (3) lymphocyte activation and regulation in adaptive immune response. Of note, certain loci and genes seem to be shared between SLE and other autoimmune disorders, including rheumatoid arthritis (RA), type 1 diabetes (T1D), Grave's disease (GD), multiple sclerosis (MS), and psoriasis (PSO), implying that common immunological mechanisms exist among some of these disease processes. In the following paragraph, we will elaborate the confirmed genetic risk loci identified to date, placed in the context of major SLE disease pathways where possible. In addition, we will highlight the recent findings that are particularly informative and discuss similarities and differences of these genetic factors between ethnic populations to gain an emerging landscape of SLE genetics.

**77.4.2.3 Complement and Immune Complexes Clearance.** Defects in apoptotic cell clearance, processing and presentation to lymphocytes lead to initiation of autoimmune response, promoting the development of SLE (78). Associations of several genetic loci have supported the importance of this theme in SLE pathogenesis: complement component genes, a cluster of Fcγ receptor genes, *CRP*, and *ITGAM*.

Complement is critical for the opsonization and clearance of autoantibody containing immune complexes (79).

The relationship between complement and SLE pathogenesis has long been noticed because low levels of complement are common immunologic features of SLE, particularly during disease flares (80,81). Complete deficiencies of the classical complement pathway genes (*C2*, *C4A*, *C4B* and *C1Q*) and complement *C3*, although rare, confer a strong genetic risk to SLE (82–85). Common CNVs in *C4A* (but not *C4B*) have been associated with SLE that a low copy number of *C4A* increases risk while a high copy number decreases risk for SLE (86). Deletion of genes encoding two regulators of the alternative complement pathway, *CFHR3* and *CFHR1* (complement regulator factor H-related 3 and 1), which may contribute to dysregulated complement activation, has been associated with increased risk of SLE in European American, African-American and Asian populations (87). In addition, common SNP of *C1Q*, *C3* or *CR2* (complement receptor 2) gene, which either confers lower serum levels of C1q or C3, or alters transcriptional activity of *CR2*, is also associated with risk of developing SLE in various ethnic groups (88–92). It appears that multiple genetic mechanisms, including gene deletion, structural variations, and SNPs, which result in low levels of these complement components, contribute to risk for SLE.

Chromosome 1q23 contains five genes (*FCGR2A*, *FCGR3A*, *FCGR2C*, *FCGR3B* and *FCGR2B*) encoding the low-affinity Fcγ receptors (FcγRs), which play critical roles in regulating a variety of humoral and cellular immune responses including immune complex clearance and antibody-dependent cellular cytotoxicity (93). Several functional variants in these genes, which may alter the binding affinities of the encoded receptors leading to a less-efficient clearance of ICs, have been reported to confer risk for SLE and/or lupus nephritis among multiple populations: a nonsynonymous variant of *FCGR2A* (H131R) (94), a nonsynonymous mutation in the mature sequence for *FCGR3A* (F158V) (95), and a nonsynonymous variant of *FCGR2B* (I187T) (96–98). However, the presence of high sequence homology between the *FCGR* genes, together with the presence of known segmental duplication in this region may preclude the assessment of specific SNPs in *FCGR* gene complex on the currently available GWAS arrays. Additionally, the presence of structural variation is another complicating factor for this locus. Association between SLE and a decreased copy number of *FCGR3B* is observed in multiple ethnic groups (99–103), which correlates with levels of protein expression and immune complex clearance (104). Further interpretations of the relative contribution of various *FCGR* variants to SLE must be made in the context of LD involving multiple functional variants.

**77.4.2.4 TLR/IFN Signaling in Innate Immune Response.** Innate immune system activation including increased type I interferon (IFN-α) production has been implicated in SLE pathophysiology, which is supported by a range of studies (105–107). The overproduction of

GWAS, genome-wide association studies; NA, not applicable; ND: not determined; OR, odds ratio; SLE, systemic lupus erythematosus.

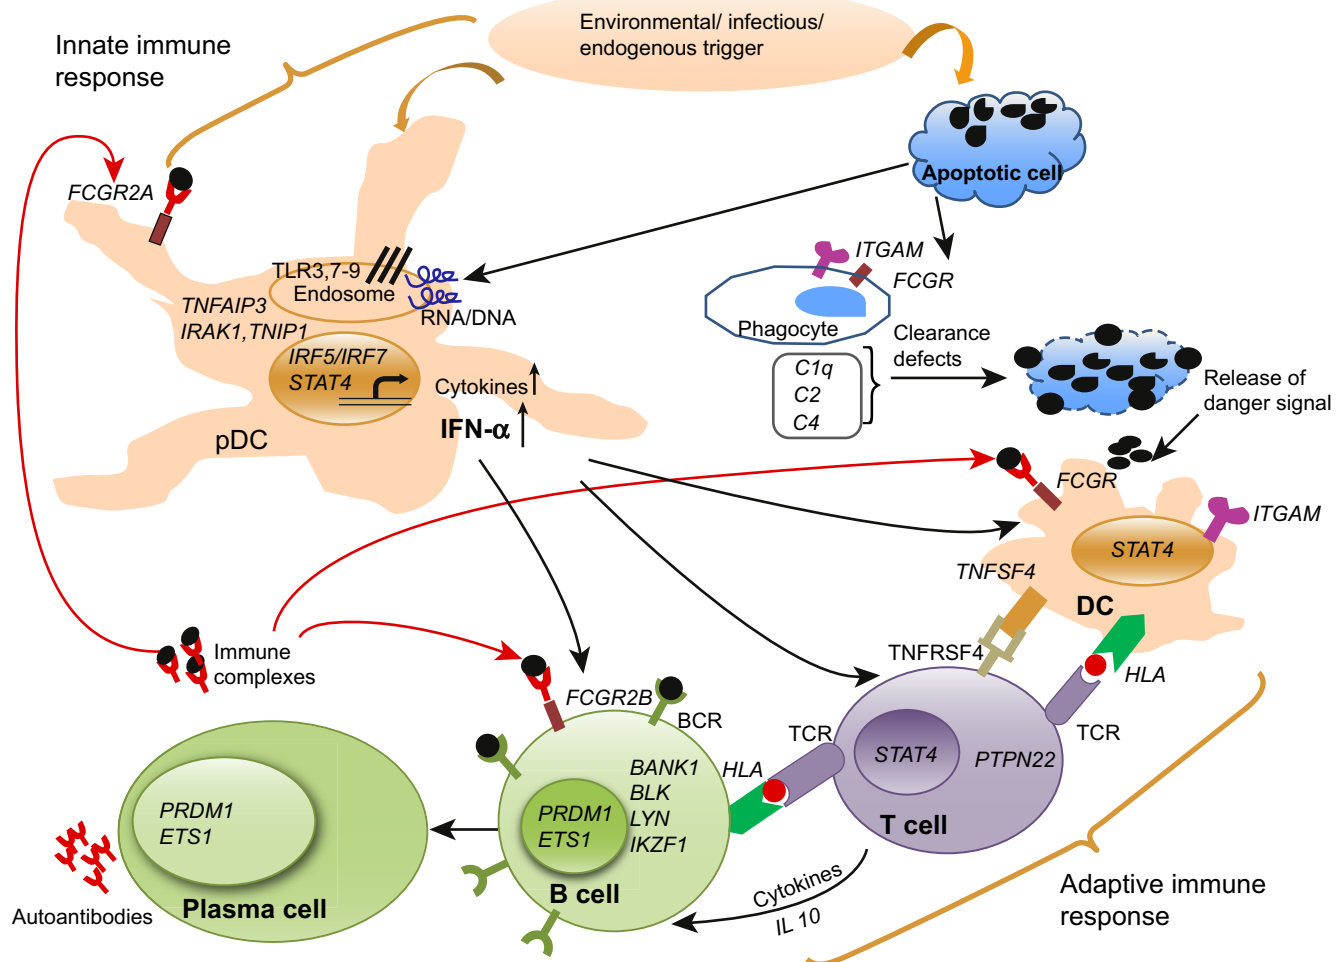

<sup>a</sup>Replication followed by initial GWA scan to calculate joint *P* values in a single publication.

<sup>b</sup>Loci identified through candidate gene studies and GWAS.

<sup>c</sup>Have not been replicated independently at the time of writing.

<sup>d</sup>Replication conducted in 740 SLE trio pedigrees.

<sup>e</sup>It is a large-scale replication study using a similar cohort to the Hom et al. (50).

**FIGURE 77-1** A model of SLE-associated genetic variants in the immune response. This model is highlighted by the identified SLE susceptibility loci, based on current understandings of important immunological pathways involved in SLE pathogenesis. Clearance and processing of immune complexes: environmental triggers that induce apoptosis and release of nuclear antigens can stress phagocytes (including macrophages and neutrophils), causing defective clearance of nuclear antigens. TLR/IFN signaling in innate immune response: environmental triggers including UV light, demethylating drugs and viruses can yield stimulatory DNA or RNA that activates TLRs, resulting in secretion of type I IFN. Lymphocyte activation and regulation in adaptive immune response: an adaptive immune response begins with the presentation of nuclear antigens to dendritic cells, leading to the generation of autoantibodies and immune complexes that in turn amplify both innate and adaptive immune responses. Abbreviations: BCR, B-cell receptor; DC, dendritic cell; IFN, interferon; IL, interleukin; pDC, plasmacytoid dendritic cell; SLE, systemic lupus erythematosus; TCR, T-cell receptor; TLR, Toll-like receptor.

IFN- $\alpha$  can promote dendritic cells maturation, autoreactive B- and T-cells activation, and proinflammatory cytokines and chemokines expression (108). The major source of excess IFN- $\alpha$  production in SLE is induced by immune complexes containing self-antigens and nucleic acids, which bind to endosomal Toll-like receptors (TLR7 and TLR9) and further activate transcription factors of the IFN pathway (such as IRF5/7, NF- $\kappa$ B and STAT4). Several specific genes with influence on IFN pathway and related innate immune signaling functions have been identified to associate with SLE susceptibility, which will enhance our understanding of genetic contribution to this dysregulated pathway predisposing to SLE.

**77.4.2.4.1 IRF5.** Interferon regulatory factor 5 (IRF5; encoded by *IRF5*), a pivotal transcription factor in the type I IFN pathway, regulates the expression of IFN-dependent genes, inflammatory cytokines and

genes involved in apoptosis. *IRF5* is one of the most strongly and consistently SLE-associated genes outside the MHC region, conferring a modest risk with an OR  $\geq 1.5$  (Table 77-4). Four functional *IRF5* variants, including a 5-bp indel (insertion/deletion) near the 5' untranslated region (UTR), rs2004640 in the first intron, a 30-bp indel in the sixth exon and rs10954213 in the 3' UTR, have been identified in association studies derived from multiple ethnic groups (109–117). Alleles of these functional variants in different combinations defined various haplotypes that are associated with increased, decreased, or neutral levels of risk for SLE. The SLE-risk haplotypes of *IRF5* have functional consequences, including increased expression of *IRF5* mRNA and interferon-inducible chemokines, as well as elevated IFN- $\alpha$  activity (118,119). Indeed, a required role for *IRF5* in mediating lupus pathogenesis

is demonstrated in murine models of lupus-like disease using *Irf5*<sup>-/-</sup> MRL/lpr mice (120), or *Irf5*-deficient and *Irf5*-sufficient *FcγRIIB*<sup>-/-</sup> Yaa mice (121).

**77.4.2.4.2 STAT4.** *STAT4* encodes the signal transducer and activator of transcription 4 protein (STAT4), which transmits signals from the receptor for type I IFN, IL-12 and IL-23, and can contribute to autoimmune responses by affecting the functions of several innate and adaptive immune cells (122). The SNP (rs7574865) in the third intron of *STAT4* is first identified for association with SLE in several case-control studies, exhibiting an OR of 1.5–1.7 (123–126), and has been subsequently confirmed by GWAS using populations of European or Asian ancestry (51–55). This rs7574865 risk variant is associated with a more-severe SLE phenotype characterized by disease-onset at a young age (<30 years), a high frequency of nephritis, the presence of antibodies toward dsDNA (124,126,127), and/or an increased sensitivity to IFN- $\alpha$  signaling in peripheral blood mononuclear cells (PBMCs) (128). Fine-mapping studies have led to the identification of several markers that are independently associated with SLE and/or with differential levels of *STAT4* expression (127,129,130), and a 73-kb-risk haplotype common to European Americans, Koreans and Hispanic Americans (130). Of note, individuals carrying one or more risk alleles of both *IRF5* and *STAT4* variants have an increased risk for SLE (127), suggesting multiple genes in the type I IFN pathway may interact predisposing to SLE.

**77.4.2.4.3 PHRF1/IRF7.** Two independent studies of European populations have reported an SLE-associated SNP (rs4963128) in a gene of unknown function named PHD and RING-finger domains 1 (*PHRF1*, also known as *KIAA1542*) (51,53). The observed association might be attributable to its close proximity with interferon regulatory factor 7 (*IRF7*), because the strong LD ( $r^2=0.94$ ) between this disease-associated SNP and a 3' UTR *PHRF1* SNP (rs702966) is within 0.6-kb flanking region of the *IRF7* gene (51). *IRF7*, similar to *IRF5*, is a transcription factor that can activate transcription of IFN- $\alpha$  and IFN- $\alpha$ -inducible genes downstream of endosomal TLRs. Supporting *IRF7* as an SLE susceptibility gene comes from two studies: (1) SLE patients carrying *PHRF1* risk alleles and expressing SLE-associated autoantibodies to dsDNA or anti-Sm exhibit elevated serum IFN- $\alpha$  activity (131), and (2) the major allele of a nonsynonymous SNP (Q412R) in *IRF7* confers elevated IFN-stimulated response in vitro and predisposes to SLE in Asian, European American and African-American populations (132). However, a complete assessment of the *PHRF1/IRF7* locus with dense genetic markers and/or sequencing is still pending to localize all possible causal variants.

**77.4.2.4.4 TNFAIP3 and TNIP1.** *TNFAIP3*, the tumor necrosis factor alpha inducible protein 3 gene, encodes the zinc finger A20 protein which is a ubiquitin-modifying enzyme critical for termination of NF- $\kappa$ B responses downstream of signal transduction through

tumor necrosis factor receptor (TNFR), TLR, IL1R (interleukin 1 receptor) and nucleotide-binding oligomerization domain containing 2 (NOD2) (133–135). Reduced A20 expression predisposes to autoimmunity as is shown in mice with B-lymphocyte-specific A20 ablation, which exhibits elevated numbers of germinal center B cells, autoantibodies and glomerular immunoglobulin deposits (136). In humans, GWA studies have suggested *TNFAIP3* as a susceptibility locus for SLE (52,54,55). Independent genetic associations of the *TNFAIP3* region with SLE in European population have been localized to a region 185 kb upstream of *TNFAIP3*, which was also associated with RA (137,138), a region 249 kb downstream of *TNFAIP3* (139) and a 109-kb haplotype spanning the *TNFAIP3* coding region, which harbors a putative causal variant in exon 3 (rs2230926, Phe127Cys) (52,140). By fine mapping and genomic resequencing in ethnically diverse populations, Adrianto et al. have further characterized the *TNFAIP3*-risk haplotype and identified a TT>A dinucleotide (deletion T followed by a T–A transversion) as the best candidate polymorphism responsible for the association between *TNFAIP3* and SLE in subjects of European and Korean ancestries (141). The TT>A dinucleotide variant, 42 kb downstream of the *TNFAIP3* promoter, is located in a region of high conservation and regulatory potential that may influence *TNFAIP3* expression by altering the binding of a nuclear protein complex composed of NF- $\kappa$ B subunits. *TNFAIP3*-interacting protein 1 (encoded by *TNIP1*) is involved in inhibition of NF- $\kappa$ B activation by interacting with A20 (encoded by *TNFAIP3*). Recent GWAS have revealed association of *TNIP1* with SLE in both Chinese and European-derived populations (53,54).

**77.4.2.5 Regulators of Lymphocytes in Adaptive Immune Response.** SLE is characterized by a loss of T- and B-cell tolerance, accounting for the formation of autoantibodies. GWAS have identified multiple SLE susceptibility genes involved in T- and B-cell signal-transduction pathways, which illustrate the importance of the differentiation, activation or function of various lymphocytes participating in the SLE pathogenesis.

**77.4.2.5.1 PTPN22.** *PTPN22* encodes tyrosine-protein phosphatase nonreceptor type 22, a lymphoid-specific phosphatase that inhibits T-cell activation. The 620Trp allele of the nonsynonymous SNP rs2476601 (Arg620Trp) is associated with a risk of developing multiple autoimmune diseases, including SLE, RA, GD and T1D, providing evidence for shared mechanisms despite their diversely different clinical presentations (142). The association between rs2476601 and SLE has been confirmed in European (51,53), but not in Asian GWAS (54,55), possibly attributable to a high variability in 620Trp allele frequencies among populations (European: 2–15%, Asian: nearly absent). The substitution of Arg with Trp at the amino acid 620 increases the intrinsic lymphoid-specific phosphatase activity of *PTPN22* that reduces the signaling threshold for T-cell receptor

(TCR) and promotes the development of autoimmunity (143). Supporting this notion, the Arg263Gln variant of *PTPN22* that reduces the phosphatase activity of *PTPN22* and increases the threshold for TCR signaling has been associated with protection against SLE in European populations (144). A connection between *PTPN22* and the type I IFN pathway has been suggested on the basis of elevated serum IFN- $\alpha$  activity in SLE patients carrying the 620Trp allele (145).

**77.4.2.5.2 *TNFSF4*.** TNF ligand superfamily member 4 (encoded by *TNFSF4*, also known as OX40L) expressed on antigen-presenting cells interacts with its receptor, TNF receptor superfamily member 4 (OX40L receptor), present on cell surfaces of activated T cells to induce the production of costimulatory signals. OX40L-mediated signaling induces B-cell activation and differentiation as well as IL-17 production, but inhibits the generation and function of IL-10-producing CD4<sup>+</sup> type 1 regulatory T cells (146). An SLE-risk haplotype defined by tag SNPs in the upstream region of *TNFSF4* is identified using both case-control and family-based European-derived samples, which correlates with increased expression of OX40L (147). Increased OX40L levels may predispose to SLE either by augmenting the interaction between T cells and antigen-presenting cells, or by influencing the functional consequences of T-cell activation via the OX40L receptor (147). Subsequently, associations between the *TNFSF4*-tagging SNPs and an increased risk for SLE have been confirmed in a GWAS of Chinese populations, a European replication study (53,54), and four independent SLE datasets from Germany, Italy, Spain and Argentina (148). These consistently observed robust associations warrant further studies to localize causal variants, and to understand how these *TNFSF4* polymorphisms affect the pathogenesis of SLE.

**77.4.2.5.3 *BLK*, *BANK1* and *LYN*.** *BLK* encodes B-lymphocyte-specific tyrosine kinase (Blk), a member of the Src family kinases, which functions in intracellular signaling and regulates the proliferation, differentiation and tolerance of B cells. Two SLE-associated SNPs of *BLK* have been identified in GWAS of European populations (50,51): one is rs13277113, located in the intergenic region between *FAM167A* and *BLK*, of which A allele is associated with reduced expression of *BLK* but increased expression of *FAM167A* in SLE patients; the other is an intronic SNP of *BLK*, rs2248932, located 43 kb downstream of rs13277113. Both SNPs have been subsequently confirmed for association with SLE in Asian populations (55,149,150).

*BANK1* encodes an adaptor/scaffold protein primarily expressed in B cells. *BANK1* protein regulates direct coupling between the Src family of tyrosine kinases and the calcium channel IP3R, and facilitates the release of intracellular calcium, altering the B-cell activation threshold (151). It is also identified as a binding partner of tyrosine-protein kinase Lyn (encoded by *LYN*), which plays an essential and rate-limiting role in mediating B-cell

inhibition by phosphorylation of CD22 and recruitment of SHP-1 (Src homology domain (SH)-1-containing tyrosine phosphatase) (152). GWAS in European populations have led to the identification of *BANK1* and *LYN* variants associated with SLE (51,76). Three functional *BANK1* variants including a nonsynonymous SNP in the IP3R binding domain (rs10516487; Arg61His), a branch point-site SNP (rs17266594; located in an intron), and another nonsynonymous SNP in the ankyrin domain (rs3733197; Ala383Thr), predispose to the sustained activation of B-cell receptors and the subsequent B-cell hyperactivity commonly observed in SLE (76). With the exception of the rs10516487 SNP of *BANK1*, which showed a weak association with SLE in an Asian GWAS (55), the remaining SNPs of *BANK1* and *LYN* have not been confirmed in Asian GWAS, partly owing to the low frequencies of the SNPs in Asian population (54,55). It is tempting to postulate that multiple B-cell-specific gene variants may interact, contributing to aberrant regulation of B-cell signaling commonly observed in SLE patients.

**77.4.2.5.4 *ETS1* and *PRDM1*.** *ETS1* encodes *ETS1* protein, a member of the ETS family of transcription factors, which inhibits the function of PR domain zinc finger protein 1 (encoded by *PRDM1*, also known as *BLIMP1*) that negatively regulates B-cell and T-helper-17-cell differentiation (153,154). Of interest, *PRDM1/ATG5* has been identified as a risk locus for SLE in both European and Asian GWAS (51,53,54), while genetic associations within *ETS1* region have been reported only by GWAS in Asians (54,55). The SLE-risk allele A of the *ETS1* variant (rs1128334; located in the 3' UTR) is associated with decreased *ETS1* expression levels in PBMCs from normal healthy controls (55). The importance of *ETS1* in SLE pathogenesis is further supported using *Ets1*-deficient mice that developed a lupus-like disease characterized by high titers of autoantibodies and local activation of complement (155).

**77.4.2.5.5 *IKZF1*.** DNA-binding protein Ikaros (encoded by *IKZF1*) is a member of a family of lymphoid-restricted zinc-finger transcription factors that regulates lymphocyte differentiation and proliferation, as well as self-tolerance through regulation of B-cell-receptor signaling (156). *IKZF1* is identified as a novel SLE susceptibility locus in a Chinese GWAS (54), and in large replication studies of European-derived populations (53). Decreased expression of *IKZF1* mRNA has been observed in PBMCs from patients with SLE (157), however, the role for *IKZF1* in the pathogenesis of SLE requires further study.

**77.4.2.5.6 *IL10*.** *IL10* encodes interleukin-10 (IL-10), which inhibits T-cell function by suppressing the synthesis of proinflammatory cytokines such as TNF $\alpha$ , IL-1, IL-6, IL-8, and IL-12 (158), inhibits antigen-presenting cells by downregulating MHC-II and B7 expression (159), and promotes B-cell-mediated functions, enhancing survival, proliferation, differentiation and antibody production (158). Of interest, increased IL-10 production by peripheral blood B cells and monocytes is observed in patients

with SLE and associated with disease activity (160), which could explain B-cell hyperactivity in SLE. A study of the molecular mechanisms underlying this increase in IL-10 production led to the identification of *IL10* haplotypes (defined by three SNPs in the *IL10* promoter region) that associated with variability in IL-10 production (161). Associations between these *IL10* SNPs and SLE susceptibility have been reported in European, Hispanic American and Asian populations (162–164). A large-scale replication study in populations from the USA and Sweden has confirmed *IL10* as an SLE susceptibility locus (53).

**77.4.2.6 X Chromosome Genes.** The striking ratio of approximately 9 females to 1 male for SLE susceptibility might be attributed to direct or indirect effects of sex hormones and/or X-linked genes. The first experimental evidence for sex chromosome related to SLE risk came from a report that showed increased autoimmune disease in mice with XX sex chromosome complement, as compared to XY, regardless of the gonadal sex (testes or ovaries) (165). In support of this idea, Scofield and colleagues found overrepresentation of Klinefelter's syndrome (men with more than 1 X chromosome; 47,XXY) among men with SLE and possibly decreased risk of SLE in X0 Turner's syndrome women (166,167). Recent studies have reported the genetic contributions for SLE on the X chromosome genes including *IRAK1*, *MECP2* and *TLR7*.

**77.4.2.6.1 *IRAK1* and *MECP2*.** *IRAK1* encodes a serine–threonine protein kinase named IL-1 receptor-associated kinase 1, which regulates multiple pathways in both innate and adaptive immune responses by linking several immune-receptor complexes to TRAF6 (TNF receptor-associated factor 6) (168). Studies by Jacob et al. provide an important insight into *Irak1* function in murine models of SLE as *Irak1* could play a role in regulation of nuclear factor  $\kappa$ B (NF $\kappa$ B) in TCR signaling and TLR activation, as well as in the induction of IFN- $\alpha$  and IFN- $\gamma$  (169). Additionally, they tested the candidacy of *IRAK1* as an X chromosome-encoded risk factor for SLE in humans. In studying ~5000 subjects of four different populations, five SNPs spanning *IRAK1* gene showed disease association in both adult-onset and childhood-onset SLE (169). Located in the region of LD with *IRAK1* is another potential risk gene for SLE, methyl-CpG-binding protein 2 (*MECP2*), which has a critical role in the transcriptional suppression of methylation sensitive genes (170). A large replication study in a European-derived population confirmed the importance of this region (*IRAK1*–*MECP2*) to SLE although further work is required to identify the causal variants (53).

**77.4.2.6.2 *TLR7/TLR8*.** Toll-like receptor 7 (*TLR7*), and its functionally related gene *TLR8* encode proteins that play critical roles in pathogen recognition and activation of innate immunity (171). They recognize endogenous RNA-containing autoantigens and induce the production of IFN- $\alpha$  (172). There is compelling evidence supporting the contribution of *TLR7* to the development of SLE. Transgenic mice with a twofold

overexpression of *Tlr7* accelerate to develop spontaneous autoimmunity (173), whereas *Tlr7*-deficient mice have ameliorated lupus disease, decreased lymphocyte activation, and decreased serum IgG (174). In addition, inhibitors of *Tlr7* can reduce a number of lupus-associated phenotypes both in the MRL and NZB/W lupus-prone strains (175). However, the finding that a genomic duplication of *Tlr7* associated with an increased severity of lupus-like disease in murine models was not translated to humans with SLE. A CNV study in multiple ethnic groups showed that the CN of *TLR7* varied in both SLE patients and normal controls, but it was not significantly increased among SLE patients compared to controls (176). Fine mapping the genomic region containing *TLR7* and *TLR8* led to the identification of a functional polymorphism in 3' UTR of *TLR7* that conferred elevated expression of *TLR7* and predisposed to the development of SLE in Asians (177). Similar studies in other ethnic populations are underway to elucidate variants within the *TLR7/TLR8* region for risk of SLE.

**77.4.2.7 Other Loci.** GWAS in multiethnic groups have revealed several SLE-associated loci appear to be unique to a specific ethnic group, such as *PXK* (PX domain containing serine/threonine kinase), *XKR6* (XK, Kell blood group complex-related family member 6), *JAZF1* (juxtaposed with another zinc finger gene 1) and *UHRF1BP1* (UHRF1-binding protein 1) in Europeans (51,53), but *RASGRP3* (RAS-guananyl-releasing protein 3) and *WDFY4* (WDFY family member 4) in Asians (54,55). Functions of these novel genes are neither fully characterized nor obviously connected to the known pathways contributing to SLE. To elucidate the underlying mechanisms by which these genes increase the risk for SLE will help to establish novel relationships to the disease pathogenesis.

**77.4.2.8 SLE Subphenotypes with Currently Known Susceptibility Loci.** SLE is a genetically complex disease with heterogeneous clinical manifestations. Following the GWAS that have greatly expanded the number of established SLE-risk loci, recent studies have begun to characterize cumulative associations of multiple risk loci and their relationship to SLE subphenotypes. Anti-double-stranded DNA (anti-dsDNA) autoantibody, an SLE-related autoantibody with diagnostic and clinical importance, is observed in 40–60% of SLE patients. A GWAS performed in European-derived population has identified robust genetic associations with SLE based on anti-dsDNA autoantibody production (178). SNPs of *STAT4*, *IRF5*, *ITGAM* and *HLA* are strongly associated with anti-dsDNA<sup>+</sup> patients, but fewer and weaker associations are observed for anti-dsDNA<sup>−</sup> patients. SNPs in *BANK1*, *PHRF1* and *UBE2L3* show associations only in anti-dsDNA<sup>+</sup> patients. These data suggest that many established SLE-susceptibility loci may confer disease risk through their roles in autoantibody production. By analyzing 22 previously established SLE-susceptibility loci, Taylor and his colleagues defined a genetic risk score (GRS) for SLE as the number of risk alleles

with each weighted by the SLE risk OR (179). Additionally, they studied associations of the individual risk allele and the GRS with clinical manifestations for patients. Their analysis categorizes SLE subphenotypes into three groups: those associated with GRS (cumulative risk loci) including age at diagnosis, anti-dsDNA autoantibody, oral ulcers, immunological and hematologic disorders; those associated with single-risk loci including renal involvement and arthritis; and those with no known genetic associations such as serositis, neurologic disorder, photosensitivity, malar and discoid rash (179).

**77.4.2.9 Shared Loci between SLE and Other Autoimmune Disease.** Paralleling the GWAS of mapping SLE-risk loci are the success in identifying genetic associations among other autoimmune diseases including RA, systemic sclerosis (SSc), primary antiphospholipid syndrome (APS), Behcet's disease (BD), T1D, inflammatory bowel disease (IBD), Crohn's disease (CD), ulcerative colitis (UC), GD and PSO. The identification of risk loci shared between SLE and other autoimmune disorders provides the possibility that common immunological mechanisms exist among some of these disease processes (Table 77-5). For example, a cluster of

genes involved in T-cell activation may increase susceptibility to autoimmune disease generically: *HLA class II* with multiple autoimmune diseases (180) (reviewed in Chapter 76); *PTPN22* with SLE, RA, GD, SSc and T1D (143,181–183); *TNFSF4* with SLE and SSc (184). More recently, the newly developed “ImmunoChip” array contains 184 loci with >200,000 SNPs representing genetic associations identified from one or more of 12 different inflammatory phenotypes, including SLE, RA, T1D, CD, UC, PSO, primary biliary cirrhosis, autoimmune thyroid disease, MS, celiac disease, IgA deficiency, and ankylosing spondylitis. The availability of this new platform will accelerate the identification of shared variants between multiple autoimmune diseases, and loci that promote disease-specific phenotypes.

## 77.5 GENE EXPRESSION PATTERNS ASSOCIATED WITH SLE

The association between type I IFN pathway activation and SLE has been demonstrated by a number of studies, showing (1) upregulated IFN-inducible gene expression patterns (known as IFN signature) in SLE blood cells (106,185–187), (2) increased serum IFN- $\alpha$  activity (188), and (3) elevated serum levels of IFN-regulated chemokines (189,190). The activation of type I IFN pathway appears to be associated with disease flares at a single time point of cross-sectional studies (191,192). However, longitudinal studies reveal that the IFN signature does not fluctuate with marked clinical changes (193,194), suggesting that upregulation of IFN-inducible gene expression is not a dynamic component of the SLE disease process, but a relatively stable characteristic (193). It is likely that a robust IFN signature provides a pro-flare environment but is insufficient to trigger rapid disease exacerbation (194). There may be additional factors precipitating disease flares in the context of IFN-mediated biochemical changes. Recent advances in SLE genetics have helped define specific SLE-associated genetic variants with functional relationships to IFN production or responses in patients. Given the proposed pivotal role of IFN in SLE, therapeutics targeting the IFN pathway is in development for the treatment of SLE, including ongoing clinical trials to test monoclonal antibodies that bind to IFN- $\alpha$  (195,196).

## 77.6 PREGNANCY COUNSELING OF SLE PATIENTS

In general, pregnancies in SLE do not exacerbate the disease. Flare rates of SLE during pregnancy are approximately 25%, which is similar to flare rates in nonpregnant SLE patients (197,198). Preexisting clinically active disease and nephritis are the main features that predict maternal complications (197,198). Preeclampsia/eclampsia as a pregnancy complication occurs in approximately 10% of lupus nephritis patients (198). Mutations in

**TABLE 77-5 SLE Loci Shared with Other Autoimmune Diseases**

Function	Gene	Location	Disease
Clearance of immune complex	<i>FCGR2A</i> <sup>a</sup>	1q23	T1D, UC
	<i>FCGR3A</i> <sup>a</sup>	1q23	RA
Regulation of Innate Immunity

	Intergenic ( <i>IKZF1</i> )	7p12	CD
Cytokine	<i>IL10</i>	1q31–q32	UC, T1D, BD

These loci were identified through GWAS, GWA meta-analysis studies, candidate gene studies or replication papers.

GWAS, genome-wide association studies; IBD, inflammatory bowel disease; IFN, interferon; NF- $\kappa$ B, nuclear factor  $\kappa$ B; pAPS, primary antiphospholipid syndrome; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; SS, primary Sjögren's syndrome; SSc, systemic sclerosis; T1D, type 1 diabetes; TLR, toll-like receptor; TNF, tumor necrosis factor; UC, ulcerative colitis.

<sup>a</sup>All genetic variants at the shared loci are common across the listed diseases.

complement regulatory proteins, including membrane cofactor protein, and complement factor I predispose to preeclampsia in SLE (199). Increased synthesis of complement (C3, C4) by the liver during pregnancy can mask the drop in complement levels that indicate an impending disease flare. Changes in levels of estrogen, prolactin, and other hormones that have complex interactions with the immune system may affect the disease course. It is recommended that patients with SLE attempt pregnancy only during periods of disease quiescence, and if renal, cardiac and pulmonary functions are not impaired.

Although there is no known teratogenic effect of SLE itself, maternal transfer of autoantibodies can cause damage to a developing fetus. Antiphospholipid antibodies and lupus anticoagulant are prevalent in lupus patients and have been implicated in recurrent fetal loss and thrombosis (200). Maternal transfer of antiphospholipid antibodies can cause fetal loss and intrauterine growth retardation (201). A few SNPs in *BLK* and *STAT4* genes that predispose to SLE also predispose to APS (without SLE) (202). Transfer of maternal anti-Ro (SS-A) and/or anti-La (SS-B) antibodies can cause injury to the atrioventricular node of a fetal heart, leading to the development of congenital heart block (CHB) during the eighteenth through twenty-fourth weeks of gestation (203). Because only 2% of pregnant women with antibodies to SSA/SSB deliver babies with CHB, it has been thought that maternal genetic predisposition is also required, and studies have suggested that several genes in the HLA region are involved (204). However, the development of CHB in a fetus grown in a surrogate mother who was anti-Ro-positive suggests that in some cases, the antibody itself can be pathogenic (203). Buyon reviewed studies of mothers of children with CHB and concluded that mothers who have both anti-Ro (SS-A) and anti-La (SS-B) antibodies are at higher risk for infants with CHB than mothers with either autoantibody alone (201). It is not unusual for mothers of infants with neonatal lupus to be asymptomatic. In a neonatal lupus research registry, 35% of mothers (39 of 110) were asymptomatic at the time CHB was identified in their infants. After a mean follow-up of 8 years, 14 of the 39 mothers (36%) developed symptoms of a rheumatic disease, while the majority (64%) remained asymptomatic (201). Therefore, pregnant women with SLE should be assessed for the presence and the titer of antiphospholipid antibodies (especially of the IgG class, with a history of intravascular thrombosis or prior fetal loss) because of risk for fetal loss, as well as for presence of anti-Ro (SS-A) and anti-La (SS-B) antibodies because of the small risk for CHB. Genetic determinants for the ability to make antiphospholipid and anti-SSA/SSB antibodies autoantibodies are only partially understood. The majority of association studies between MHC class II alleles and the production of specific autoantibodies to Ro, La, and phospholipid have shown that (i) the presence of both anti-Ro (SS-A) and anti-La (SS-B) is associated with HLA-B8, DR3, DRw52, and DQw2 (201), (ii) the

presence of anti-Ro (SS-A) alone is mainly associated with DR2 and DQw1 (201,205), and (iii) the presence of various antiphospholipid antibodies is associated with DR4, DR7, DRw53, and DQB1\*0302 (206). Results from these studies have not reached a point where they can be used to successfully predict fetal risk for neonatal lupus or for CHB. Thus, genetic counseling for families of SLE patients cannot offer precise risk figures yet.

## 77.7 CONCLUDING REMARKS

In the past few years (2007–2011), collaborative efforts among investigators in the field of lupus genetics have made it possible to conduct large-scale, case-control association studies using both the candidate gene approach and GWAS, establishing over 30 confirmed loci including many novel loci. Despite the tremendous progress, there remain several challenges for the future studies. (1) The disease-associated variants identified in current GWAS are almost common SNPs (frequency > 5%) and not all of them are likely to be the causal variants. Next-generation sequencing of an associated region will be needed to reveal unknown variants, including rare SNPs with a prevalence <1% and other polymorphisms (including insertion/deletion, copy number, and repeat element variations) which could also contribute to SLE. (2) It is important to note that many of the GWAS associations detected so far have been in European or Asian populations. Additional studies using large samples of diverse ethnic populations, particularly African and Hispanic ancestries, are also required. This will help clarify the basis for disparities of SLE association between different populations and provide a better understanding of the genetic basis of SLE. (3) GWAS have not only highlighted the importance of shared biological pathways in the pathogenesis of SLE and some of other autoimmune diseases but also implicated the involvement of previously unrecognized pathways. Understanding the contribution of each associated genetic locus in the context of complex molecular pathways and networks that lead to higher order clinical disease will improve current medical practice in providing pregnancy counseling, personalized care and treatments for patients affected with SLE in the near future.

### Biographies

**Yun Deng, MD** is a postdoctoral scholar of the Department of Medicine, Division of Rheumatology at UCLA. Her current research includes the identification of susceptibility genes for systemic lupus erythematosus (SLE) and elucidating the molecular mechanisms underlying these identified genetic risk factors that affect disease pathophysiology.

**Bevra H Hahn, MD** is a professor of Medicine, Vice-Chair of the Department of Medicine, and Chief of Rheumatology at UCLA. She is past-president and a Master of the American College of Rheumatology. Dr Hahn provides clinical consultations for patients with rheumatic diseases, particularly SLE. Her current research includes investigations in genetics, pathogenesis, and treatment of SLE, as well as clinical trials in new therapies for accelerated atherosclerosis.

**Betty P Tsao, PhD** is a professor of Medicine of the Department of Medicine, Division of Rheumatology at UCLA. Her current research includes the identification of human chromosomal regions containing susceptibility genes for systemic lupus erythematosus (SLE). Genetic susceptibility is the single greatest risk for SLE. Her laboratory has gathered approximately 300 families that contain two or more members with SLE. Recently, she has shown that the human chromosome 1q regions are likely to contain multiple genes predisposing to SLE, and discovered that Asian males, in particular, with a variant form of the X-linked gene “Toll-like receptor 7 (TLR7)” are at increased risk of developing SLE. Dr Tsao is currently studying the role of X-linked genes in gender bias of SLE, functional consequences of SLE-associated variants, and the genome-wide association studies of Asians in SLE.

## GLOSSARY

**Anticitrullinated peptide antibody (ACPA)** – Citrulline is a nonstandard amino acid derived by posttranslational deimination of arginine by the enzyme peptidylarginine deiminase. Compared to rheumatoid factor, ACPA are more specific (95%) and equally sensitive (67%) serological biomarkers of RA.

**Enteropathic arthritis** – Inflammatory arthritis related to inflammatory bowel disease (e.g. Crohn's disease or ulcerative colitis).

**Endoplasmic reticulum aminopeptidase 1 (ERAP1)** – (a.k.a. ARTS-1 (Type 1 tumor necrosis factor receptor shedding aminopeptidase regulator)) A gene with a highly significant association with HLA-B27 positive ankylosing spondylitis. Protein for which it codes trims peptide antigens to optimal length for binding to HLA class 1 molecules.

**Felty syndrome** – Disease complex of rheumatoid arthritis, lymphadenopathy, neutropenia, and splenomegaly.

**Fibroblast-like synoviocyte (FLS)** – Cells within the synovial intimal lining which are key players in the inflammation and joint destruction in rheumatoid arthritis.

**Genome-wide association studies (GWAS)** – These studies involve systematic genotyping of a large number of SNPs with minor allele frequency >1% across the entire genome; comparison between patients with disease and healthy controls aims to identify genetic loci over- or underrepresented in the case cohort.

**Receptor activator of nuclear factor- $\kappa$ B (RANK)** – Receptor on surface of osteoclasts for **receptor activator of nuclear factor- $\kappa$ B ligand (RANKL)**. RANKL binding to RANK induces differentiation of osteoclast precursors into osteoclasts, and activates mature osteoclasts.

**Rheumatoid factor (RF)** – Antibody against the Fc portion of IgG.

**Seronegative spondyloarthropathy (SpA)** – Group of inflammatory conditions including ankylosing spondylitis, reactive arthritis, enteropathic arthritis, and psoriatic arthritis. They are characterized by a number of common features including inflammation of the

entheses; prominent axial and asymmetric lower limb peripheral large-joint arthritis; extra-articular features including uveitis; the formation of new bone at the site of inflammation; and association with the MHC class I gene HLA-B\*27. AS is the hallmark SpA.

**Severe combined immunodeficiency (SCID)** – A group of rare genetic diseases in which both B cells and T cells are deficient resulting in marked susceptibility to recurrent and overwhelming infection.

**Shared epitope (SE)** – All rheumatoid-associated DR molecules (encoded by DRB1\*0401, \*0404, \*0405, \*0408, \*0101, \*0102, \*10, and \*1402) share an identical or similar sequence between amino acids 67 and 74, <sup>67</sup>LLEQRRAA<sup>74</sup>. This sequence codes for a highly conserved sequence along the  $\alpha$ -helix derived from the DR $\beta$  chain, which forms one side of the antigen-binding site of the DR molecule.

**Tumor necrosis factor  $\alpha$  (TNF $\alpha$ )** – A cytokine with a central role in inflammation.

## 78.1 INTRODUCTION

The inflammatory arthropathies described in this chapter are multifactorial polygenic disorders. In recent years, the application of genome-wide association studies (GWAS) has played an important part in identifying many of the genes involved. Associations with human leukocyte antigens (HLAs) were first described in 1973 although the precise mechanisms by which these cause disease are still unclear. The association with protein tyrosine phosphatase PTPN22 is now well established as the second strongest with rheumatoid arthritis (RA) and is particularly a good example of an association that is common to several autoimmune conditions. There is now convincing evidence for the involvement of more than 30 genes in RA and at least 14 in ankylosing spondylitis (AS). Many of these are key factors in the regulation of inflammatory and immunological responses, as expected, but others have less-obvious biological expectations. The association of RA

with HLA-DRB1 alleles is robust and its interaction with smoking as an environmental factor is strongly suggested. The association of AS with several genes in the IL-17 producing (Th17) lymphocyte subset has already marked this as a potential therapeutic target (1). The highly significant association of AS with ERAP1 has provided an important example of gene–gene interaction in susceptibility to a complex disease since the association is entirely restricted to those individuals with AS who also carry HLA-B\*27 (2). This association has also been evaluated at the level of protein structure and function. ERAP1 variants associated with protection against AS have reduced ability to trim peptide antigens to optimal length for binding to HLA class 1 molecules (3). This raises the possibility that inhibitors of ERAP1 could be protective against AS.

## 78.2 RHEUMATOID ARTHRITIS

Clinical descriptions of RA appeared fairly late in the medical literature and it was only distinguished from gout and osteoarthritis by Garrod 200 years ago. Classical RA is characterized by a destructive inflammatory arthritis affecting the synovial joints, but a wide spectrum of severity exists. The substantial variation in clinical features and severity of the disease underlines the likelihood that its etiology is also heterogeneous, including the genetic factors that are involved. Familial clustering of cases is well recognized, with a generally accepted fivefold excess sibling recurrence risk over the general population risk ( $\lambda_s \sim 5$ ) although this varies with the severity of the disease in the proband.

Typically, RA presents as a distal small-joint arthropathy of the hands (Figure 78-1) and feet that may initially involve relatively few joints. Subsequently, the more proximal load-bearing joints become involved, potentially leading to severe functional disability. Any synovial joint, including the temporomandibular and cricoarytenoid joints, may be affected. Overall the disease is approximately three times more common in women than

men, but this varies with the age of onset. Thus, at the age of 30 years, women are nearly 10 times more frequently affected than men, while there is no gender difference in incidence by the age of 65 years. RA may present in many different ways. In about two-thirds of cases, there is pauciarticular, insidious onset (typically in the hands and feet) with cumulative joint involvement over the course of months/years. This may be difficult to distinguish from other self-limiting causes of synovitis in the early stages of the disease. In contrast, the onset is explosive in a small minority of cases who develop widespread symmetrical polyarthritis over a few days or even overnight. Despite this dramatic onset, a proportion of such cases eventually show complete resolution of synovitis and little joint destruction a year or two later. Systemic features, including fever, weight loss, and malaise, occasionally dominate the onset of RA, particularly in middle-aged men, prompting extensive investigation to exclude alternative causes, such as deep-seated infection or malignancy. Limb girdle symptoms similar to polymyalgia rheumatica may be prominent, particularly in those with later-onset disease. Occasionally, patients present with “palindromic rheumatism;” this consists of short-lived attacks (~48 h) of mono-, oligo- or polyarticular synovitis that initially resolve completely but recur at intervals and may eventually persist. Positive tests for rheumatoid factor (RF) and anticitrullinated protein antibodies (ACPAs) are predictive of progression to persistent rheumatoid disease.

Extra-articular features are common in RA. These include skin nodules, cachexia, and normochromic, normocytic anemia. Mild peripheral neuropathy with glove-and-stocking sensory loss is more common than mononeuritis multiplex caused by rheumatoid vasculitis of the vasa nervorum. Major rheumatoid vasculitis affects men more commonly than women and can cause life-threatening cutaneous ulceration, myocardial infarction, or bowel ischemia. Serositis is relatively common in RA; pericardial effusions are often asymptomatic and have been reported in up to 30% of those with RA on echocardiography. Rarely, constrictive pericarditis may result, and the heart valves are occasionally affected, particularly in those with nodular disease. Corticosteroids may be required to treat symptomatic pleurisy or pericarditis. About 20% of patients develop secondary Sjögren syndrome with keratoconjunctivitis sicca and/or xerostomia. The eyes are commonly affected by episcleritis, which usually requires no treatment, but, less commonly, there may be scleritis, which may require systemic corticosteroids or immunosuppression. Lymphadenopathy is common, but <1% of patients develop Felty syndrome (RA, lymphadenopathy, neutropenia, and splenomegaly). This disorder rarely develops <10 years from the onset of RA (4). Patients with Felty syndrome probably suffer joint disease of similar severity to non-Felty patients, but have more extra-articular manifestations. Familial recurrence of RA is more common where the proband has Felty syndrome.

**FIGURE 78-1** Classical rheumatoid deformity of the hands with ulnar deviation and subluxation at the metacarpophalangeal joints.

Historically, despite active treatment with standard disease-modifying drugs, <50% of those with RA have been able to work full-time after 10 years of disease. Mortality is also increased by about 50%, reducing life expectancy by about 11 years (mainly as a result of increased cardiovascular disease and infections). New approaches to treatment with antitumor necrosis factor biologics have had a dramatic effect on joint disease in RA that may eventually be reflected in better mortality statistics too.

### 78.2.1 Pathology

Despite intensive research, the pathophysiology of RA remains incompletely understood. Animal models of the disease have provided some useful insights, including the central role of tumor necrosis factor  $\alpha$  (TNF $\alpha$ ) in rheumatoid inflammation. Such models are imperfect, however, and much useful information has been gleaned from careful studies of the disease in humans and from dissecting the genetic basis of the disease in GWAS.

There is convincing experimental and clinical evidence of involvement of many cell types, including macrophages, B lymphocytes, T lymphocytes, and synovial fibroblasts, all of which are overrepresented in RA synovium. In RA, the normal synovial lining expands from 1–3 to 10–15 cell layers, which is predominantly composed of macrophages and synovial fibroblasts; the additional influx and proliferation of immune and resident synovial cells also contribute to synovial hyperplasia. The most abundant stromal cells are the fibroblast-like synoviocytes (FLS) that appear abnormally resistant to apoptosis and accumulate in the RA synovium. Activated FLS are detectable early on in rheumatoid disease and although multiple factors from both the innate (primarily TLR2) and adaptive (e.g. TNF $\alpha$ , IL-1, IL-6 and IL-17) immune systems support FLS activation, at least part of FLS activation appears to be independent of the surrounding inflammatory tissue (5). FLS activation leads to the upregulation of numerous chemokines (MIP-1 $\alpha$ ), cytokines, matrix metalloproteinases, and adhesion molecules (integrins, VCAM-1 and cadherins) required for the recruitment of inflammatory cells and their destructive effects in the joint (6). In particular, the production of interleukin (IL)-15 by FLS induces the production of other cytokines, such as TNF $\alpha$  and IL-17, by T cells through direct cell–cell contact. This further stimulates the expression of IL-15 and IL-6 by FLS, creating a feedback loop that favors persistent inflammation (7). Microarray analysis has suggested two subgroups of FLS distinguished by their gene expression signatures. FLS from highly inflamed areas have a TGF $\beta$ -activin A-inducible signature characteristic of myofibroblasts (which have a particular propensity for chemokine and cytokine production), while FLS from less-inflamed synovial tissue have a predominance of insulin-like growth factor-regulated genes (8).

Classification of RA synovial tissue histomorphology has been attempted according to differential synovial infiltration by leukocyte populations. Most patients with RA have diffuse sublining infiltration consisting of scattered CD4 T lymphocytes and monocytes, but a significant proportion (up to 25% in some series (9)) develop more discrete synovial aggregates with T- and B-cell compartmentalization. Intriguingly, these aggregates can progress into ectopic lymphoid structures resembling germinal centers with characteristic follicular dendritic cell networks and proximity to high endothelial venules. A recent study using a severe combined immunodeficiency (SCID) mouse model suggested that these follicles are functional, not only expressing activation-induced cystidine deaminase (AID), the key enzyme in somatic hypermutation and class-switch recombination of immunoglobulin genes, but also supporting the production of ACPA (10). Unfortunately, differences in clinical study design and classification of aggregates have thus far led to contradictory findings on the correlation of lymphoid neogenesis with disease- or treatment-response phenotypes in RA. Indeed, lymphoid neogenesis may simply represent a bystander effect in any form of local inflammation (and interestingly such aggregates may also be found in patients with psoriatic arthritis, which is not held to be an autoantibody or B-cell-mediated disease). Despite this, some homogeneity does indeed exist and the synovium as a potential biomarker for disease severity or treatment response remains a tantalizing possibility.

The hypertrophic synovium develops into invasive pannus, eroding the articular cartilage and bone, particularly at the points of synovial attachment, causing loss of joint space, instability, and deformity. Accumulation of osteoclasts at sites of bone erosion is characteristic. These multinucleated cells express receptor activator of nuclear factor- $\kappa$ B (RANK) and are derived from CD14-positive cells of monocyte/macrophage lineage under the influence of macrophage/monocyte colony-stimulating factor, RANK ligand (RANKL), and inflammatory cytokines. Increased numbers and activity of osteoclasts are both hallmarks of inflammatory bone loss. The inflammatory milieu within the RA joint also serves to augment not only osteoclast precursor recruitment from bone marrow but also their subsequent differentiation into mature osteoclasts. Mature osteoclasts secrete hydrochloric acid to dissolve inorganic bone matrix, while the bone matrix proteins are degraded by proteolytic enzymes (e.g. matrix metalloproteinases and cathepsin K). The main sources of RANKL are osteoblasts, FLS and activated T cells and its expression in these cells is upregulated by proinflammatory cytokines in synovial tissue, including IL-1, IL-6, IL-17 and TNF $\alpha$ . Such cartilage and bone loss is manifested radiologically by juxta-articular osteoporosis, narrowing of the joint space and the development of erosions and joint deformity (Figure 78-2); however, the relationship between synovial inflammation and articular erosion is complex and variable. Occasionally,

**FIGURE 78-2** Radiographic appearances of advanced rheumatoid arthritis.

patients with prolonged synovitis do not erode, while erosions may be apparent in others at the time of presentation. Erosive disease is more common in those who are HLA-DRB1\*04 positive.

Angiogenesis is a key event in the maintenance of synovial inflammation, delivering nutrients and immune cells to the site of inflammation. Despite new vessel formation, inflamed synovial tissue is invariably hypoxic: synovial proliferation leads not only to increased metabolic demand but also regional hypoperfusion as tissue hyperplasia increases the distance between proliferating cells and infiltrating vessels. The resultant low tissue oxygen tension drives the transcription of hypoxia-inducible factor (HIF) regulated genes, not least vascular endothelial growth factor (VEGF), the most potent proangiogenic molecule.

The complex pathophysiology of RA has been amply demonstrated in recent years by the efficacy of several different immunomodulatory drugs that target discrete elements of the immune system. These include biologic agents targeting cytokines, such as TNF $\alpha$  (therapeutic monoclonal antibodies and a recombinant TNF receptor/Ig fusion protein) and the IL6 receptor; T-cell activation (recombinant CTLA4/Ig fusion protein); and B cells (anti-CD20 agents).

### 78.2.2 Diagnostic Criteria

RA is regarded by many as a heterogeneous group of conditions with overlapping phenotypes. Over the years, many attempts have been made to define the disease

**TABLE 78-1** 2010 American College of Rheumatology/European League against Rheumatism Classification Criteria for Rheumatoid Arthritis (15)

**Score  $\geq 6/10$  required for classification as definite RA:  
Add scores A–D**

**A. Joint involvement**

1 large joint **0 points**; 2–10 large joints **1 point**; 1–3 small joints **2 points**; 4–10 small joints **3 points**;  $>10$  joints including at least 1 small joint **5 points**.

**B. Serology**

Negative RF and negative ACPA **0 points**; Low positive RF or low positive ACPA **2 points**; high positive ( $>3$  times upper limit of normal) RF or high positive ACPA **3 points**.

**C. Acute-phase reactants**

Normal CRP and ESR **0 points**; Abnormal ESR or CRP **1 point**.

**D. Duration of symptoms**

$<6$  weeks **0 points**;  $\geq 6$  **1 point**.

Adapted from Aletaha, D.; Neogi, T.; Silman, A.; et al. 2010 Rheumatoid Arthritis Classification Criteria: An American College of Rheumatology/European League Against Rheumatism Collaborative Initiative. *Arthritis Rheum.* 2010, 62, 2569–2581.

more accurately using classification criteria, including those developed by the American College of Rheumatology (or its antecedents and collaborators) in 1958, 1987 and 2010. Comparisons between population studies are therefore somewhat complicated by differences in the diagnostic criteria that have been used. The 2010 American College of Rheumatology/European League Against Rheumatism classification criteria (Table 78-1) have a high degree of sensitivity and specificity. They have been modified particularly to detect early disease more effectively than the previous criteria because it is now recognized that early treatment of RA can prevent irreversible joint damage (11). The diagnosis is not difficult in typical cases once the disease has been present for several months, but in early disease, a confident diagnosis may be difficult, particularly where there is palindromic onset, limited synovitis or normal inflammatory markers. As many as one-fifth of patients presenting at an early synovitis clinic may turn out not to have RA after 1 year or so (12,13). The recognition that ACPA occur with high frequency in RA has led to their development as diagnostic aids in early inflammatory arthritis. ACPA have a similar sensitivity to RF for RA [ $\sim 80\%$ ] but are more specific [ $\sim 98\%$ ]. Both RF and ACPA may precede the development of clinical disease by months or years (14).

### 78.2.3 Differential Diagnosis

The diagnosis of RA is relatively straightforward except in the early phase, when distinction from self-limiting arthropathies (e.g. reactive arthritis, viral arthropathies, and crystal arthropathies) may be more difficult.

Distinction from the seronegative arthropathies, notably psoriatic arthritis and reactive arthritis, may sometimes be problematic. Generalized nodal osteoarthritis is occasionally similar and may coexist with RA; typically it affects the proximal and distal interphalangeal joints but usually spares the metacarpophalangeal joints and wrists. Osteoarthritis affecting the knees and hips is very common and is partly genetic in origin; large-joint osteoarthritis requiring joint replacement has an excess sibling recurrence risk of 2.3 (16).

Crystal arthritis is common and may be difficult to distinguish from RA, particularly in the elderly. For example, gout is polyarticular in onset in 10% of cases and quite commonly is not associated with elevated uric acid levels in the acute phase. On the other hand, its typical presentation with monoarticular lower limb arthropathy is quite distinct (50% of initial attacks involve the great toe, “podagra”). The diagnosis is correctly established by demonstrating intracellular needle-shaped crystals of monosodium urate in aspirates from affected tissues that are strongly negatively birefringent under polarized light. It is strongly familial, and its genetic etiology is reviewed in Chapter 95. Pyrophosphate arthropathy may cause a “pseudorheumatoid” pattern of chronic arthropathy, as well as the more widely recognized acute episodes of “pseudogout,” which can also punctuate the more chronic forms of pyrophosphate arthropathy. The diagnosis of crystal arthritis is best established by aspiration of the affected joint and demonstration of the relevant intracellular crystals under polarized light. Familial forms of chondrocalcinosis, characterized by early-onset pyrophosphate arthropathy, often have a dominant inheritance pattern. Some are linked to chromosome 5p (17), where gain-of-function mutations in ANKH, encoding a transmembrane transporter of inorganic pyrophosphate, have been described. Polymorphic variants of ANKH are also associated with sporadic forms of pyrophosphate arthritis (18). Pyrophosphate arthropathy is also a classic component of hemochromatosis (Chapter Iron Metabolism and Related Disorders), in which abnormal iron handling causes its deposition in numerous tissues, including the liver, myocardium, and synovium. The defective HFE gene is a member of the immunoglobulin superfamily and has a very high mutant allele frequency (~0.1) in northern Europe. Premature degenerative arthritis, particularly in atypical sites, such as the metacarpophalangeal joints, wrists, and ankles, should raise suspicions, especially if articular calcification is present. The diagnosis is best established by demonstrating saturation of transferrin and elevated ferritin levels. Elevated ferritin levels alone may be spurious, since ferritin, an acute-phase reactant, is commonly elevated in inflammatory states including RA.

#### 78.2.4 Population Prevalence

Depictions of RA in art and literature seem to be lacking until about 200 years ago in Europe. As a consequence,

there has been speculation that the disease appeared relatively late in Europe and may even have been imported from the New World. RA has rarely been identified convincingly in the archeological record, but it may be mistaken for other diseases. Nonetheless, there is some evidence that the disease existed in Egypt in the third millennium B.C. and also in Roman Britain (19).

The disease has a peak incidence in the age of 40–50, but may present at almost any age. There is an excess of incidence in the puerperium, and it has been suggested that oral contraceptives may confer some protection. Although most women also experience remission in pregnancy, unfortunately, recrudescence in the puerperium is almost invariable and may be severe.

The prevalence of RA in many populations worldwide is remarkably similar (~1%), but with some important exceptions that may give clues to the etiology of the disease. Environmental and/or genetic factors could account for the variations in the prevalence observed in certain ethnic groups (20,21). For example, the disease is rare in most of sub-Saharan Africa (prevalence = 0.3%) but common in certain American Indian groups (5–7%). South African blacks in a rural environment exhibit the same low prevalence of the disease as in most of sub-Saharan Africa. This contrasts starkly with the high frequency of the disease in their urban counterparts, similar to that in South Africans of European descent, which strongly suggests an environmental influence. By contrast, the high frequency of RA in the Chippewa and Yakima Indians of North America may be due to the high frequency of certain HLA class II alleles (see Section 78.2.5.2.1) associated with RA: HLA-DRB1\*04 and the rare HLA-DRB1\*1402 allele, respectively (22,23). In most populations that have been studied, there are strong associations with various HLA-DRB1\*04 alleles (relative risk ~5) (21,24,25). The HLA-DRB1\*04 series, originally defined serologically as the HLA-DR4 transplantation antigen, can be subdivided into numerous HLA-DRB1 alleles, not all of which are associated with rheumatoid. Thus, HLA-DRB1\*0402 (originally defined as Dw10 in the mixed lymphocyte reaction) is the dominant HLA-DRB1\*04 subtype in Jews, but since DRB1\*0402 is not associated with RA, there is no apparent association of RA with DRB1\*04 overall in Jews, as discussed in Ref. (26). In contrast, associations are seen with HLA-DRB1\*01 and HLA-DRB1\*10 in Jews, which are relatively weaker associations in other populations where the association with HLA-DRB1\*04 is more obvious. The rarity of HLA-DRB1\*04 in Nigeria could account for the low incidence of RA in this population, but by contrast, in nearby Gambia, where HLA-DRB1\*04 is relatively common (~15%), RA is still very rare (our own survey in the 1990s revealed only one case in 2000 individuals). This suggests that either non-HLA genetic effects and/or environmental factors are also important. Indeed, it has been speculated that chronic stimulation of the immune system by tropical infections, including malaria, may in

some way be protective against the development of autoimmunity (27). The lack of geographic case clustering is in stark contrast to other forms of inflammatory arthritis, such as Lyme disease (28) or postenteric reactive arthritis (see Section 78.3.3), in which there is a clear evidence for an infective trigger. No convincing epidemiologic data have yet been provided to support a role for infection although it is widely believed that microbial agents are involved (29). Several viruses, including Epstein–Barr virus, rubella, and parvovirus B19, can cause acute and occasionally more persistent arthropathies, but neither viruses nor bacteria have been consistently isolated from the joints of affected individuals.

## 78.2.5 Genetics

Concordance rates in monozygotic twins vary between studies from 12% to 30%, which is not surprising in view of the different methodologies used. In the United Kingdom in the 1960s, concordance in identical twins with seropositive erosive disease was estimated as 30% (30). This contrasts with a lower rate of 12% obtained in a nationwide survey of twins in Finland that included individuals with less-severe disease (31). A more recent UK study (32) found 15% concordance in identical twins and demonstrated that this was highest in those twin pairs that were HLA-DRB1\*04 positive (33). In all of these studies, the rates for monozygotic twin concordance were four to five times higher than for dizygotic twins, highlighting the likely importance of genetic factors. There seems little doubt that nongenetic factors are important, not only in the development of RA but also in its progression. On the basis of these relatively small studies, broad sense heritability has been estimated to be about 55% (34).

**78.2.5.1 Sibling Recurrence Risk.** Sibling recurrence risk varies according to the severity of the disease in the proband. In Lawrence's UK studies in the 1960s (30), the excess risk to the sibs of individuals with mild nonerosive seronegative disease was barely greater than the general population frequency ( $\lambda_s$  1.1). This is increased to sixfold in the siblings of individuals with seropositive, erosive disease, where as many as 15% of individuals will have an affected first-degree relative (35). Family recurrence risks of RA are also around seven times greater when the proband has Felty syndrome and are probably also increased when the index case has early-onset disease. The observation that the sibs of those with RA who share both HLA haplotypes identical by descent with the proband are at particular risk (36) is especially interesting as this group may be more likely than others to be HLA-DRB1\*04 homozygous (37,38). The excess sibling recurrence risk over the general population risk ( $\lambda_s$ ) is critically dependent on the criteria used in diagnosis. Thus mild, nonerosive disease is relatively common in the community at large and sib recurrence risks are relatively low. In contrast, seropositive, erosive rheumatoid

disease (that is typically followed up in hospital clinics) is much less common in the community and has higher sib recurrence risks. For this type of chronic, erosive disease,  $\lambda_s$  is probably nearer 12 to 14 and the genetic contribution is correspondingly higher.

**78.2.5.2 HLA and RA.** RA is clearly linked to the major histocompatibility complex (MHC) (39), as demonstrated in many populations (Table 78-2). The application of DNA-based approaches amply confirmed these linkages (40–43) and has now been applied at the genome-wide level for non-MHC loci. HLA class I associations with RA are invariably weaker than those in the HLA class II region, particularly with HLA-DRB1 alleles (21,24,25,44). With the application of high-density mapping techniques, it is now clear that there are important associations not only with HLA-DRB1 but also with the HLA-B and HLA-DP loci (45).

**78.2.5.2.1 Associations with the Classic Serologic HLA-DR (HLA-DRB1) Specificities.** Although these associations were originally defined by serology, they have been amply replicated and refined latterly at the DNA level. Associations with HLA-DRB1\*04 are well established in most ethnic groups globally, typically with a relative risk of approximately 5. Some important exceptions to this general rule have been observed, particularly among Jews (26), some Indian populations (46), Chileans (47), and the Yakima American Indians (23), in whom alternative associations have been found with DRB1\*01, DRB1\*09, and DR6 (DRB1\*1402). The association with HLA-DRB1\*09 originally described in Chileans has also been found as a minor association in the UK (48). Although the association with DRB1\*04 predominates in most populations, other weaker associations are not uncommon. Thus, associations with HLA-DRB1\*10 have been observed in Spaniards (49,50), Indians (51), and Jews (52), and with HLA-DRB1\*01 (DR1) in Indians (46,51), Jews (52,53), and southern European populations, in particular (54). While the strongest associations in the United Kingdom are with HLA-DRB1\*04, weaker associations can also be detected with both DRB1\*01 and DRB1\*10 (44,55).

**78.2.5.2.2 Differential Association of the DR4 (HLA-DRB1\*04) Allelic Subtypes with RA.** Not all DR4 haplotypes are equally associated with RA, despite the fact that SNP analysis indicates a high degree of conservation in the DNA flanking the HLA-DRB1 locus that encodes the polymorphic DR $\beta$ 1 chain (56). Thus, HLA-DRB1\*0401, \*0404, \*0408, and \*0405 are positively associated with RA, but \*0402, \*0403 and \*0407 are negatively associated (44,57,58). In the United Kingdom, there is a hierarchy of HLA-DRB1 susceptibility alleles (Table 78-3). The most widely held explanation for this observation (shared epitope hypothesis) is that there is a conserved functional epitope in the HLA-DR molecules positively associated with RA (encoded by DRB1\*0401, \*0404, \*0405, \*0408, \*0101, \*0102, \*10, and \*1402).

This analysis included 576 HLA-DRB1 alleles from the patient group and 1000 alleles from ethnically matched controls.

Adapted from Hall, F. C.; Weeks, D. E.; Camilleri, J. P., et al. Influence of the HLA-DRB1 Locus on Susceptibility and Severity in Rheumatoid Arthritis. *Q. J. Med.* 1996; 89, 821–829.

In particular, a highly conserved sequence between amino acids 67 and 74 along the  $\alpha$ -helix derived from the DR $\beta$  chain, which forms one side of the antigen-binding site of the DR molecule, is incriminated in susceptibility as shown in Figure 78-3. All the rheumatoid-associated DR molecules share an identical or similar sequence,

**FIGURE 78-3** Antigen-binding site of an HLA-DR molecule. Charged amino acids at position 71 in Dw10 (DRB1\*0402) and 74 in Dw13 (DRB1\*0403 and \*0407) abolish susceptibility to rheumatoid arthritis; noncharged substitutions at position 71 in Dw4 (DRB1\*0401) do not.

<sup>67</sup>LLEQRRAA<sup>74</sup>; with the exception of DRB1\*0401, where the substitution of a basic lysine for arginine at position 71 is a relatively conservative change. This hypothesis probably accounts for the lack of association with HLA-DRB1\*04 in Israeli Jews, in whom \*0402 is the predominant DR4 subtype. This allele encodes a quite distinct <sup>67</sup>ILEDERAA<sup>74</sup> sequence in the DR4 molecule, including two acidic substitutions, compared to HLA-DRB1\*0404/8 (57). It has therefore been speculated that the capacity of the HLA-DR molecules to bind a potentially arthritogenic peptide may trigger an autoimmune response within the synovial joint, leading to the chronic process of inflammation and destruction that ensues (24,25,58,59). Crucially, this same <sup>67</sup>LEDERAA<sup>74</sup> motif is also found in the uncommon variant of HLA-DR1 (HLA-DRB1\*0103), which is not associated with RA (44). It should be noted that the shared epitope has been associated predominantly with ACPA positivity. In addition, there is a pronounced and dose-dependent risk of smoking in individuals carrying the shared epitope in developing ACPA-positive, but not ACPA-negative, RA (60). It has been postulated that this gene–environment interaction in RA may be explained by smoke-induced citrullination of pulmonary peptides resulting in increased binding affinity to shared epitope MHC class II receptors, and thereby T-cell activation (60).

Associations with other MHC genes have been suggested by some studies. For example, it has been suggested that TNF polymorphisms might influence responses to anti-TNF therapies (61). It is extremely difficult to separate possible effects from the TNF locus and those arising from HLA-DRB1 haplotypes because of the linkage disequilibrium between the two loci (62). To achieve this, association studies must be both adequately powered and also very carefully matched for controls (e.g. for HLA-DRB1 status). We have previously suggested that there may be an extended TNF haplotype marking a 126-kb region centromeric to TNF that is particularly interesting (63). This region contains the gene AIF1, encoding allograft inflammatory factor that has previously been implicated in inflammatory states (64); however, such suggestions require very careful validation in carefully controlled, high-density genetic mapping. The longstanding suggestion that numerous HLA alleles, particularly in the MHC class II region, are involved in RA (65) has been confirmed by recent high-density mapping studies of the MHC. It is now clear that contributions arise not only from HLA-DRB1 but also from HLA-B and HLA-DP (45). It has also been possible to refine the precise epitopes within each of these HLA molecules that are associated with susceptibility. This is analogous to the complex HLA associations that have also been described with type 1 diabetes mellitus (66).

**78.2.5.2.3 Non-Inherited Maternal HLA Antigens and RA.** Despite the relatively strong association between RA and HLA-DRB1 alleles, at least 15% of patients do not carry the conserved DRB1 epitope. It has

been proposed that, in these circumstances, some form of immunogenetic modulation may occur as a result of exposure of the host immune system to the noninherited HLA-DRB1\*04 from the mother in utero (67). HLA-DRB1\*04 appears to be overrepresented among non-inherited maternal HLA antigens in patients with RA (68). It has also been demonstrated that noninherited maternal HLA-DR antigens can exert a protective effect. HLA-DR antigens containing the protective sequence <sup>67</sup>ILEDERAA<sup>74</sup> are substantially underrepresented in the mothers of those with RA. The functional significance of these observations remains to be established. It could reflect an impact on the shaping of the T-cell receptor repertoire or an influence on tolerance mediated through exposure of the developing immune system to maternal antigens resulting from long-term microchimerism (69).

**78.2.5.2.4 Associations between HLA and Disease Severity.** HLA-DR associations with RA are dependent on the method of ascertainment. Community-based surveys pick up many milder cases compared with hospital-based studies, and interesting differences are apparent in their respective HLA associations. Community-ascertained case studies find relatively weak or absent association with HLA-DR4 (70,71) in contrast to hospital-based studies, in which about 70% of patients are DR4 positive. The progression of erosions has been correlated with presence of DRB1\*04 and DRB1\*0401 (72), and twin concordance is greatest in DR4-positive identical twins (33). Patients with Felty syndrome have a particularly strong association with DR4 (up to 95%), and the DRB1\*0401 allele (>50%) in particular (73). In populations where the DRB1\*0401 is uncommon (Greeks, Chinese, and Japanese), Felty syndrome is either rare or absent. There is also an excess of DRB1\*04 homozygotes in hospital patients with the disease (37,38) that is particularly obvious in Felty syndrome (73).

**78.2.5.3 Non-HLA Genetic Contribution to RA.** The heritability of RA attributable to HLA is no greater than 40% of the whole genetic component (74–76), and in recent years, much research has been focused on identifying the remainder of this genetic contribution. Initial studies using whole genome linkage approaches had only limited success but more recent GWAS have proved very effective, identifying more than 30 genetic regions likely to be involved in the disease. It appears that there are no other major genetic effects of the size of the MHC and that the majority of loci have small effect sizes with odds ratios (ORs) ≤ 1.05.

Genome-wide linkage scans using microsatellite markers in affected sib-pair families from Europe, Japan (77), United Kingdom, and North America unsurprisingly reported varied results. The first systematic linkage study, reported by Cornélis et al. (40), identified numerous microsatellites exhibiting nominal evidence of linkage, including two (IDDM6 and IDDM9) that had previously shown suggestive evidence of linkage to insulin-dependent diabetes mellitus. The first large-scale

systematic genome scan from North America also reported overlapping linkages with other autoimmune disorders (41), but by far, the most striking linkage was with HLA, as in other similar studies. Most of these linkages were not confirmed subsequently in a UK study of 183 multicase families (43). However, there is a weak association of IDDM6 haplotypes on chromosome 18 with RA (78). A replication study from North America subsequently confirmed some of these loci in a combined analysis of 512 families (42). Evidence for linkage was seen at 1p13, 1q43, 6q21, 10q21, 12q12, 17p13, and 18q21 as well as HLA ( $5 < 10^{-12}$ ).

Two particularly striking successes have been achieved at least in part using this approach. First, susceptibility to RA was identified in the 1p13 region with a missense mutation in a hematopoietic-specific protein tyrosine phosphatase (“Lyp”) encoded by PTPN22. The risk allele PTPN22 C1858T (R620W), present in 10–17% of the white population, disrupts its interaction with a cytoplasmic tyrosine kinase and thereby alters its normal function as a negative regulator of T-cell activation (79). It is possible that there are cis-regulatory elements in PTPN22 that regulate its expression in RA (80); however, others have suggested that there is no evidence of any other effects arising from the PTPN22 locus independent of C1858T (81). It is particularly interesting that this gene is also implicated in the etiology of several other autoimmune diseases, including autoimmune thyroid disease, type 1 diabetes and SLE (82). It is also noteworthy that the association seems to be restricted to patients with RF-positive disease (83,84). Studies in the murine equivalent have shown increased T-cell activation and CD4 and CD8 accumulation in the tissues of the affected animals and the development of spontaneous germinal centers. B-cell function may also be affected (85). Second, Suzuki et al. (86) identified a linkage interval on 1p36 in RA containing four plausible candidate genes, encoding peptidylarginine deiminases, which posttranslationally modify arginine to citrulline. RA is strongly associated with the development of ACPA even before the onset of clinical disease, suggesting that citrullination could be an important etiologic factor. Strong evidence for association with PADI4 in Japanese ( $P = 0.000008$ ) has been presented although the association appears very much weaker in other populations (87,88). It has recently been suggested that PADI4 polymorphisms particularly predispose male smokers to RA (89).

**78.2.5.4 Genome-Wide Scans.** With the introduction of GWAS, the number of genetic regions implicated in susceptibility to RA has grown rapidly. The landmark study conducted by the Wellcome Trust Case Control Consortium (WTCCC) in 2007 examined cohorts of patients with a variety of common diseases, including 2000 RA patients, and 3000 controls (90). In addition to confirming the association of RA with HLA-DRB1 and PTPN22, nine novel SNPs with nominal association to the disease, and many others with modest association,

were identified. There is now compelling evidence for the involvement of dozens of regions in RA from GWAS, and meta-analysis of such data has substantiated 35 RA-risk loci in Caucasians of European origin, including HLA-DRB1, PTPN22, CCR6, TNFAIP3, and STAT4 (91). The increased power afforded by meta-analysis has also led to identification of novel RA loci, such as CD40 (92), which was later validated in a UK study (93). Recently, the Gene Relationships Across Implicated Loci (GRAIL) method has been developed and employed to confirm many genetic associations including CD28 (94). GRAIL involves statistical mining of published abstracts to identify and prioritize genes from related biological pathways (95).

On the basis of the GWAS data, it has been demonstrated that certain combinations of alleles compound RA risk, similar to the case with HLA compound heterozygosity (e.g. OR ~21 in ACPA-positive individuals with the genotype HLA-DRB1 + PTPN22 + STAT4 + TRAF1/C5) (96). In addition, differential genetic associations within seropositive disease are emerging and may provide insights into pathogenesis; for example, PTPN22 was recently found to associate primarily with ACPA positivity, while HLA-DRB1 is associated with both RF and ACPA (97).

Most of the identified genetic associations are with seropositive RA; seronegative RA may represent a pathogenetically distinct disease and further studies on this cohort are warranted. Similarly, the majority of studies have been conducted in populations of European origin. To address this, a meta-analysis and replication study was performed in the Japanese, which identified nine novel associations reaching genome wide significance ( $p < 5 \times 10^{-8}$ ), including PTPN22, CD83, NFKBIE, ANXA3, ARID5B, B3GNT2, CSF2, PDE2A-ARAP1, and PLD4 (98). Although a multiancestry comparative analysis of Japanese and European RA heritability indicated a high degree of overlap, the differential contribution of PADI4 to RA risk (see Section 78.2.5.3) demonstrates the need for GWAS in all ethnic populations (98).

It is interesting that many genetic variants conferring RA risk are associated with multiple autoimmune or inflammatory diseases, e.g. STAT4 (SLE, type 1 diabetes, inflammatory bowel disease), TRAF/C5 (SLE, JIA), and the chromosome 6q23 locus (SLE, type 1 diabetes, celiac disease) (99). A recent meta-analysis identified eight non-HLA-risk loci common to both celiac disease and RA, bringing the number of shared loci to 14 (100). Seven of these genes are also common to type 1 diabetes (101). The themes of these common risk alleles include innate immunity (e.g. TRAF/C5), T-cell differentiation (STAT4), and T-cell signaling (PTPN22) (102). It has been postulated that the unique and dominant HLA associations result in presentation of disease-specific autoantigens to T cells; the common non-HLA risk determinants may in turn influence the response of the immune cells to these autoantigens (100). In many cases, additional work is

required, including fine mapping or deep resequencing of the genetic regions of interest, to precisely identify the causative allelic variants underlying the SNP associations (99). An example is the association of RA with SNP rs6920220 on chromosome 6q23, positioned between the TNFAIP3 and OLIG3 genes (103). Subsequent fine mapping determined that there are actually three RA risk alleles within this region, one of which confers protection (104). The functional and pathogenic significance of these allelic variants also require further study.

Despite these advances, more than 50% of the genetic contribution to RA remains unexplained. This may be due to as yet unidentified rare genetic variants with large effect, or large numbers of risk alleles of small effect not yet identifiable reliably by current methods (98). The expectation that copy number variants (CNVs) would represent a significant proportion of human disease risk was recently largely discounted; a large GWAS covering approximately half of the genomic CNVs >500 bp found no association with eight common diseases (105). Further large-scale association studies with saturation mapping of the relevant loci are currently nearing completion and should further advance the field in the near future.

**78.2.5.5 Genetic Models and Pathologic Mechanisms.** The shared epitope hypothesis put forward to explain the disparate HLA-DR associations with RA (106) implies the presentation of a single or limited range of potentially arthritogenic peptides by antigen-presenting cells within the joint to a subset of T lymphocytes capable of initiating a specific inflammatory response. This would most obviously produce a dominant model of susceptibility, but several studies have cast doubt on this, suggesting that the involvement of HLA genes fits best with a recessive model (75,107). The hypothesis of HLA-DQ-mediated susceptibility would fit with this model (65) as would the role of the HLA genes in shaping the T-cell receptor repertoire by positive and negative thymic selection. Another possibility invokes molecular mimicry between the shared epitope on rheumatoid-associated DR molecules with potential triggering pathogens although firm evidence for this has not been forthcoming, and such cross-reactive immune responses have not routinely been observed.

Early reports using PCR to detect expanded T-cell populations, particularly in the rheumatoid synovial

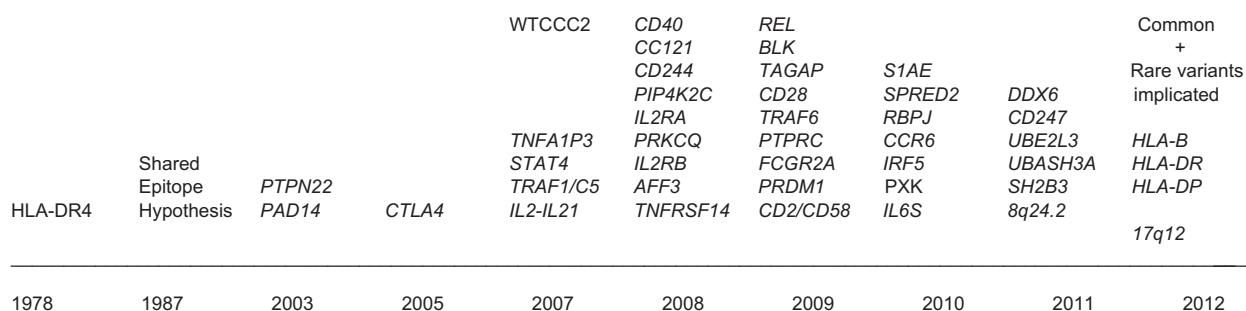

compartment, were somewhat suggestive of an antigen- or superantigen-driven response (108). Although numerous subsequent studies have sought such oligoclonal expansions in patients with RA, there seems little consistency between individual studies to support such an idea (24,109,110). This contrasts with some interesting data in reactive arthritis and psoriatic arthritis (111,112).

The association with HLA-DRB1 variants and RA suggests that engagement of specific immune responses is important at some stage in the development of the disease. It is well known that additional signaling through costimulatory molecules in this “immunologic synapse” is critical to this process. Interactions between the CD80/86 molecules on antigen-presenting cells and their potential ligands on T cells (CD28 or cytotoxic T lymphocyte associated antigen-4 (CTLA-4)) play an important role in determining activation. Variation in CTLA-4 is involved in susceptibility to autoimmune diabetes mellitus and thyroiditis. A large collaborative study from Sweden and North America suggests that there is also a weak association (OR 1.2) with RA (113). It is certainly of interest in this context that the fusion protein CTLA4Ig has impressive disease-modifying effects in RA (114). Other components of the immunologic synapse are potential candidates in the etiology of the disease. For example, CD28 is also associated with RA (94) and there is weak evidence that the inhibitory product of the programmed cell death 1 gene (PDCD1) may also be involved (115).

A list of the major genetic effects in RA identified to date is shown in Figure 78-4. Major challenges remain in the identification of all the major genetic effects in RA, particularly those attributable to rare alleles. Even weak genetic influences could herald the identification of crucial pathogenic pathways and the means to modulate them.

## 78.2.6 Management

About half of patients presenting with early undifferentiated polyarthritis have self-limiting disease, but only 15% of patients fulfilling criteria for RA go into remission (116). In those with persistent arthritis, agents that modify the course of the inflammation are required. These include sulfasalazine, methotrexate, antimalarials,

**FIGURE 78-4** Progress in the identification of genes involved in rheumatoid arthritis.

gold salts, D-penicillamine, azathioprine, and leflunomide (often used in combination). Corticosteroids (either in low doses orally or as intramuscular pulses) may be used in the early phases of the disease to suppress inflammation and erosive damage as second-line drugs are commenced (117). From the early 1990s, the treatment of the more severe forms of RA changed dramatically with the introduction of anti-TNF biologic agents (118,119). In clinical trials recruiting patients with very active disease, these drugs routinely induced remission in a quarter of patients within 3 months. Further, they could be shown to completely suppress the progression of erosions. Quite suddenly, it became unacceptable for rheumatologists to aim for anything less than complete suppression of the disease. This stimulated the use of combinations of the older disease modifying anti-inflammatory drugs, such as methotrexate, sulfasalazine and leflunomide, and if these failed to suppress the disease adequately, escalation to biologic therapies would follow. This has had a profound knock-on effect in the clinical practice of rheumatology with the development of sophisticated clinical and imaging tools to assess the degree of residual disease activity and the presence of potentially destructive synovitis. Patients are now treated much more aggressively early in the disease to prevent irreversible structural joint damage. Good responses to anti-TNF therapy can be anticipated in the majority of patients with ACR 20%, 50% and 70% responses being achieved within 3 months by 60%, 40% and 20% of patients with substantial disease activity before treatment ( $\text{DAS28} \geq 5.1$ ). In those failing anti-TNF therapy, other options with broadly comparable efficacy include rituximab, an anti-CD20 monoclonal antibody B-cell depleting agent (120), tocilizumab (anti-IL6 receptor monoclonal antibody), and abatacept (recombinant CTLA4/immunoglobulin fusion protein).

Even with the improved therapeutic armory, effective management of RA still requires a coordinated approach by a multidisciplinary team because of the chronic nature of the condition. The primary objectives are the relief of pain and preservation of function. A combination of drugs, physical therapy, orthotics, and appliances to prevent or accommodate increasing long-term disability will be required. Surgical intervention is frequently needed at some stage in the course of the disease, but requires careful planning, particularly in patients with more severe forms of the disease, who may require many procedures.

The development of reliable methods of total joint replacement, particularly in the large weight-bearing joints of the hip and knee, has otherwise been the most important single development in the treatment of patients with RA. Good results from both hip and knee replacement can be anticipated in more than 90% of patients, and, typically, the prosthesis will last for 15 years or more. Subluxation of the cervical spine is relatively common, particularly in patients with severe erosive disease, and may require surgical stabilization. The median standard mortality ratio for RA is approximately

1.5 compared with the general population (121), mainly from infection and cardiovascular disease. Only half of this can be attributed to classic risk factors such as smoking, hyperlipidemia and hypertension, all of which should be tightly controlled.

### 78.3 SERONEGATIVE SPONDYLOARTHROPATHIES

The term *seronegative spondyloarthropathy* (SpA) refers to a group of inflammatory conditions characterized by inflammation of the entheses (sites of mechanical stress where ligaments or fibrocartilage interface with bone, e.g. sacroiliac joints). In contrast to RA, RF and ACPA are absent. These two characteristics differentiate these conditions from the somewhat more common RA, which is characterized pathologically by synovitis rather than enthesitis and in which RF is present in 85%.

Other features of SpA include an association with the MHC class I gene HLA-B\*27; characteristic distribution of joint involvement with prominent axial, sacroiliac, and asymmetric lower limb peripheral large-joint arthritis; characteristic extra-articular features, particularly uveitis; and the formation of new bone at the site of inflammation, eventually leading to ankylosis. By contrast, seropositive RA is associated with the class II HLA-DRB1 genes, typically causes a small-joint symmetrical polyarthritis, has a different range of extra-articular features, and causes erosion of cartilage and bone rather than ankylosis.

Several forms of SpA are described:

1. Ankylosing spondylitis
2. Reactive arthritis
3. Enteropathic arthritis (associated with inflammatory bowel disease)
4. Psoriatic arthritis.

Some patients with SpA fail to meet the criteria for any of these individual diseases and are said to have “undifferentiated spondyloarthritis.” The features that distinguish these conditions from one another are presented in Table 78-4.

#### 78.3.1 Diagnostic Criteria

A variety of diagnostic criteria have been proposed for AS (122–124), reactive arthritis (125), and psoriatic arthritis (126,127). Criteria for AS have historically relied heavily on the presence of radiographic sacroiliitis for diagnostic specificity. As there is a mean delay of 9 years between the onset of symptoms and the development of radiographic changes, the sensitivity of these criteria in early disease is poor (128). These criteria have also been criticized for being too restrictive as they exclude a significant group of patients with clear features of SpA, but who do not clearly fit into any of the currently defined disease groups. In response to these shortcomings, the

**TABLE 78-4 Clinical Features of the Spondyloarthropathies**

	Ankylosing Spondylitis	Reactive Arthritis	Psoriatic Spondyloarthritis	Enteropathic Spondyloarthritis
Sex	M > F	M > F	F > M	M = F
Age of onset (yr)	15–35	Any age	Any age	Any age

Skin involvement	—	++	++	—
Mouth ulcers	—	++	—	+
Sacroiliitis	+++	++	++	++
Peripheral arthritis	Lower > upper	Lower > upper	Upper > lower	Lower > upper
Spinal symmetry	+++	+	+	++
Enthesopathy	++	++	++	++
Aortitis	+	+	?+	+
HLA-B*27 (%)	95	80	50	50
Risk for B*27-positive	2–8	10–20	Unknown	Unknown individual (%)
Self-limiting	—	++	—	—

—, rarely; ++, occasional; ++, frequent; ++++++, always.

Assessment of Spondyloarthritis International Society (ASAS) has developed criteria based on clinical features and magnetic resonance imaging (MRI), which are much more sensitive at picking up early disease (129). As discussed later, a combination of simple screening questions designed to identify inflammatory back pain combined with HLA-B\*27 testing and the use of MRI to detect sacroiliitis, can have a considerable impact on the diagnosis of early disease. Early diagnosis is of increasing importance since the advent of anti-TNF treatment, which can have life-changing efficacy in those with AS.

## 78.3.2 Ankylosing Spondylitis

**78.3.2.1 Epidemiology.** The most widely used diagnostic criteria for AS are the modified New York criteria (Table 78-5). Those are heavily reliant on the presence of radiographic evidence of sacroiliitis, which may take several years to develop. MRI allows much earlier detection of sacroiliac joint abnormalities, particularly active inflammation, and is the imaging technique of choice for early diagnosis (130). AS typically develops in early adulthood, with more than 90% of cases diagnosed before the age of 40 years. There is typically considerable delay in diagnosis, particularly in females among whom atypical patterns of joint involvement appear to be more common. Overall, men are also more commonly affected than women (ratio ~2.8:1). Estimates of the prevalence of AS in western Europe and North America vary between 0.05% and 1.4%, depending on study methodologies. Recent studies from Berlin suggest a prevalence of around 0.5%.

What is not in doubt is that the prevalence of AS roughly parallels the prevalence of the main susceptibility factor, HLA-B\*27, in different populations (126). Thus a high prevalence of AS is found in some populations,

**TABLE 78-5 Revised New York Criteria for Ankylosing Spondylitis<sup>a</sup>**

Low back pain ≥3 months' duration (improved by exercise and not relieved by rest)
Limited back movement (sagittal and coronal)
Reduced chest expansion (compared to age- and sex-matched values)
Bilateral sacroiliitis (grade ≥2)
Unilateral sacroiliitis (grade ≥3)

<sup>a</sup>Ankylosing spondylitis is diagnosed if significant radiographic evidence of sacroiliitis is present along with one or more clinical criteria.

Modified from van der Linden, S.; Valkenburg, H. A.; Cats, A. Evaluation of Diagnostic Criteria for Ankylosing Spondylitis: A Proposal for Modification of the New York Criteria. *Arthritis Rheum.* 1984, 27, 361–368.

including North American Indians (B27 prevalence, 18–50%), Norwegian Lapps (25–30%), and Alaskan Eskimos (25–40%). Populations with a low prevalence of HLA-B\*27, including most sub-Saharan African ethnic groups, Australian Aborigines, and South American Indians, have correspondingly low prevalences of AS. However, the relationship is not simple since other environmental and genetic factors play a significant role in the etiology of the disease. HLA-B\*27 itself is polymorphic, and there is considerable interest in the possibility that allelic differences may be responsible for different degrees of disease susceptibility associated with the B27 subtypes (see Section 78.3.2.4.1).

**78.3.2.2 Pathology.** As in all spondyloarthropathies, the basic pathologic lesion of AS is enthesitis. Enteses represent specialized areas of bone adapted to cope with stress loading at interfaces with ligaments or fibrocartilage. Enteses have large vascular beds and are the site of relatively high connective tissue metabolic activity, and are thus vulnerable to the effects of inflammation. Plasmacytic and lymphocytic infiltrates are seen. Localized

osteitis and osteoporosis occur initially. Later granulation tissue forms, fibrosis occurs, and reactive new bone formation begins. This process may continue until ankylosis occurs across the involved joint. Analogous changes occur at the attachment of the joint capsule to periarticular bone.

Although entheses and fibrocartilagenous joints are primarily affected, inflammation sometimes also involves synovial joints. In some patients, AS may even present as peripheral arthritis involving synovial joints. Eventually approximately 20% of cases develop significant hip arthritis, and involvement of the zygapophysial joints is universal. Synovial tissue from these joints shows changes similar to RA, although typically less severe. There is villous hypertrophy, synovial cell hyperplasia, and lymphocytic, plasmacytic, and histiocytic infiltration. The cellular infiltrate is diffuse, but also shows some perivascular aggregation. Although the disease is characterized systemically by raised immunoglobulin (Ig)A levels, plasma cells in the synovium secrete principally IgG. Attention has recently been drawn to the high proportion of CD4 T cells expressing the killer immunoglobulin-like receptor KIR3DL2 and their production of IL-17 (231). The synovial fluid contains fewer polymorphs and more lymphocytes than rheumatoid synovial fluid (131).

The earliest changes detectable by imaging are bone marrow edema of the sacroiliac joints (Figure 78-5) and osteitis at the vertebral corners of the spine (Figure 78-6) on fat-suppressed MRI, which reflect underlying inflammation. On plain radiographs, the earliest changes are sclerosis and erosions in the juxta-articular bone, but these may take years to develop. In the sacroiliac joints, erosions are seen as irregular variations in the width of the sacroiliac joint space and loss of clear definition of the joint line. This is usually most obvious in the inferior iliac aspect of the synovial component of the joint. Late

disease is characterized by new bone formation underneath inflamed periosteum; this is reflected on plain radiographs by “squaring” of the vertebral bodies (loss of the normal concave anterior surface) and the presence of syndesmophytes. In the sacroiliac joints, radiographs demonstrate periarticular sclerosis and later ankylosis. MRI scans may also show fibrosis and fatty replacement of the periarticular bone marrow but are inferior to plain radiographs in demonstrating the extent of new bone growth (syndesmophytes) (Figure 78-7).

**78.3.2.3 Other Clinical Features.** Osteoporosis is common in AS, often from an early stage (132–134). Spinal fractures are common in advanced disease (135), reflecting both increased bone fragility and reduced flexibility. The eye is the most common extraskelletal site of involvement in AS. Anterior uveitis (involving the structures anterior to the lens—the iris and ciliary body) occurs in around 40% of cases of AS and 5–10% of cases of reactive arthritis (136). It runs a relapsing/remitting course, is usually easily treated with cycloplegics and topical steroids, and is rarely sight-threatening unless neglected.

**FIGURE 78-5** Tilted coronal STIR MRI of sacroiliac joints showing bone marrow edema (high signal) before (A) and after (B) anti-TNF therapy.

**FIGURE 78-6** “Shiny corners” demonstrated on sagittal STIR MRI of the thoracolumbar spine due to osteitis in ankylosing spondylitis.

**FIGURE 78-7** Florid syndesmophytes contributing to the appearance of a “bamboo spine” in long-standing AS.

Idiopathic anterior uveitis is also strongly associated with HLA-B\*27 (95%) independent of AS.

Other uncommon overt extraskelatal manifestations of AS include cardiac and proximal aortic involvement by fibrosis and endarteritis. This rarely results in clinically significant reduction in left ventricular function. Heart block and aortic regurgitation due to dilation of the aortic valve ring are described and may be dramatic in onset. Standardized mortality rates are increased by about 50% in AS, much of which is due to the increased risk of cardiovascular disease. Pulmonary involvement is predominantly mechanical because of the fusion of the costovertebral joints and thoracic kyphosis, reducing vital capacity. AS is occasionally complicated by upper lobe pulmonary cavitation or fibrosis (~1% of cases), which is usually of little clinical significance but may need to be distinguished from pulmonary tuberculosis or aspergillosis.

**78.3.2.4 Genetic Studies.** A major role for genetic factors in the etiology of AS is emphasized by the high recurrence risks for AS among close relatives of patients (126,137). Several relatively small twin studies have suggested a significant genetic component to AS. The largest study, undertaken in the UK, estimated monozygotic twin concordance at 75% compared to only 12.5% of dizygotic twins. Even in B27-concordant dizygotic twins, concordance for AS was only 27%. Variance modeling using these data suggests that broad sense heritability for AS is in excess of 92%, and that HLA-B\*27 accounts for less than half of the genetic contribution (138). Environmental factors are probably important but are very common or ubiquitous, therefore playing little part in determining population variance. It has become increasingly apparent that the genetic contribution to AS is polygenic. At least two HLA genes have already been clearly demonstrated to increase susceptibility to AS. HLA-B\*27 was the first in 1973 (139,140). Subsequently, HLA-B\*60 has also been shown to be associated with AS in both B27-positive and -negative individuals (141,142), although this has not been a universal finding (143,144). Our results from a large UK survey suggest that HLA-B\*60 is associated with a two- to threefold excess risk (145).

**78.3.2.4.1 HLA-B\*27.** In the United Kingdom, more than 90% of patients with AS carry HLA-B\*27 (relative risk ~160), but only 2–8% of B27-positive individuals develop AS. The incidence of reactive arthritis (see Section 78.3.3) following bacterial enteritis may be as high as 20% in B27-positive individuals, who are also at increased risk of subsequent AS. The fact that relatively few B27-positive individuals develop B27-related diseases probably reflects the role of other genes, rather than the environmental exposure.

There are at least 70 different HLA-B\*27 alleles, differing from one another by between one and eight amino acids, which have evolved from the ancestral HLA-B\*2705 subtype (146). Different ethnic groups

have distinct subtype distributions. In most white populations, more than 90% of B27 alleles are HLA-B\*2705 and the remainder almost entirely HLA-B\*2702.

Association between AS and most HLA-B\*27 subtypes has been described, at least sporadically, (particularly HLA-B\*2702, \*2704, and \*2705), although systematic studies have not always been possible because of the rarity of some subtypes, such as HLA-B\*2701, \*2707, and \*2708. There has been particular interest in two subtypes (B\*2703 and \*2709) that appeared to be less obviously associated with AS. Early suggestions that the HLA-B\*2703 allele might not be associated with AS were based on the relatively high frequency of this allele in The Gambia where, nonetheless, AS is extremely rare (147,148), although sporadic cases of the disease in B\*2703-positive individuals have been reported in neighboring Senegal. Approximately 50% of the B27-positive individuals in The Gambia carry the most common white subtype, HLA-B\*2705, which is positively associated with disease in all other populations studied so far. Despite this, AS is vanishingly rare in The Gambia, perhaps suggesting the influence of other protective genetic or environmental effects in this population. In Europe there is good evidence from Sardinia that HLA-B\*2709 is protective against AS (149).

As a diagnostic test, HLA-B\*27 has a low positive predictive value, unless the patient already has a moderately high prior probability of disease. When the pretest probability of spondylitis is 0.5, the presence of B27 increases the likelihood of the disease to 0.92, whereas a negative result reduces it to 0.08 (150). When the prior probability is low (e.g. in population screening programs), the main use of the test is its negative predictive value. In the clinical situation of early SpA with a suspicious history and examination but normal radiographs, a positive B27 test increases the probability from as low as 0.12 to only slightly greater than chance (0.62), adding very little to the clinical decision-making process (151). Rudwaleit et al. have developed a very useful algorithm for the diagnosis of early AS, based on simple clinical questions to identify inflammatory back pain, HLA-B\*27 typing and MRI of the spine (Table 78-6) (152). The other setting in which B27 tests may be useful, is in determining the likelihood of the offspring of patients developing AS themselves. The pretest probability here is only 0.1, and positive testing for B27 increases this to only 0.2. A negative result makes it highly unlikely that the individual will develop disease and may in some circumstances be reassuring and justified.

Many theories have been proposed to explain the association with HLA-B\*27, but none is universally accepted (153). Doubts about whether HLA-B\*27 itself was directly involved or whether it was a marker for a nearby linked gene have been resolved. Transgenic HLA-B\*27-positive rats have proved susceptible to an SpA-like condition, albeit one in which inflammation of the bowel, psoriasisform skin lesions, and orchitis are prominent in

addition to peripheral arthritis (154). Although these rats only develop disease if a relatively high copy number ( $>10$ ) of the B\*27 transgene is present, no other gene is inserted and control animals do not express disease with high copy numbers of other HLA class I alleles (155). Some doubts remain about the relevance of the model to human disease, but further insights could come from study of this or other animal models (156). For example, the genetic background of the transgenic animal influences susceptibility; Dark Agouti strains of rat transgenic for HLA-B\*27 are susceptible, but this is lost when they are backcrossed with other strains. Rats bred in sterile conditions also fail to develop the disease, consistent with the hypothesis that exposure to common bacteria or even gut commensal organisms might trigger disease. It has also been suggested that cell-surface expression of HLA-B\*27 may not be necessary for the development of SpA since  $\beta_2$ -microglobulin knockout mice ( $\beta_2m^{-/-}$ ) can develop disease ( $\beta_2m$  is necessary for the stability of the B27 heavy chain (HC), with which it noncovalently associates) (157). Suggestions that presentation of B27-derived peptides by HLA class II molecules could account for this observation seem unlikely because class II knockouts can also get disease. Molecular mimicry has been expounded as a plausible theory for many years as the description of antibodies cross-reacting between *Klebsiella* species and HLA-B27. Initial reports of an increase in *Klebsiella* carriage in the stools of patients with active AS have not been reproduced, and such

cross-reactive antibodies seem unlikely to account for the tissue specificity of AS. Most likely, the role of HLA-B\*27 in antigen presentation plays an important part. In common with other HLA class I molecules, HLA-B27 binds antigenic peptides (typically 9-mers) derived from self-proteins and presents them to CD8-positive T lymphocytes for immune surveillance. Viral and tumor antigens are particularly detected in this way. Precisely how HLA-B\*27-associated antigens might trigger the disease is not clear, but CD8-positive T cells with specificity for organisms have been identified in the joints of patients with reactive arthritis (158). In contrast to other class I molecules, HLA-B27 can exist in atypical forms. B27 can form homodimers ( $B27_2$ ) that are not associated with  $\beta_2m$ , through a disulfide bond between Cys67 residues (159). How these homodimers induce AS remains unknown. They are known to be expressed at the cell surface, and may be involved in aberrant antigen presentation or in triggering the innate immune system (160). Conditions that may increase the chances of  $B27_2$  formation include peptide deficiency; excess HCs, as seen in the B\*27 transgenic rat (161); or  $\beta_2m$  deficiency, seen in the B\*27 transgenic  $\beta_2m^{-/-}$  mouse (162).

The possibility that other genes within the MHC, in addition to HLA-B\*27 and HLA-B\*60, play a role remains somewhat controversial. Weak associations with HLA-DRB1\*01 (OR 1.5; 95% confidence interval, 1.1–2.0), and the possibility that there is an extended B\*27 haplotype containing another relevant locus have been suggested (163,164); however, subsequent data from large-scale GWAS do not lend much support.

**78.3.2.4.2 Other genes.** Since genetic predisposition to AS is polygenic and B27 accounts for less than half of heritability, it is reasonable to screen the remainder of the genome for susceptibility candidates. In 1998, we published our initial genome screen on 120 affected sib-pairs in 105 families (165,166). Linkage with HLA was confirmed, but six other regions outside the MHC showed some evidence of linkage, with LOD scores of  $>1.00$ . The peak non-MHC linkage was on chromosome 16q (LOD = 2.6). Nominal linkage to the CYP2D6 microsatellite on chromosome 22 was found, and subsequent linkage and association studies with intragenic CYP2D6 markers have also proved positive (167). This gene (otherwise known as *debrisoquine hydroxylase*) is one of the cytochrome P-450 enzyme complex genes. The poor metabolizer phenotype is found in 6% of the UK population, but how this might contribute to the etiology of AS is unclear.

Initial attempts to identify non-MHC genes using linkage analysis of affected sib-pair pedigrees met with only limited success. Subsequent meta-analysis of all published studies of linkage analysis was undertaken, which confirmed highly significant linkage to the MHC ( $p < 3 \times 10^{-7}$ ) but also suggested linkage ( $p < 7.4 \times 10^{-4}$ ) to regions on chromosome 6q, 10q and 16q. Several other regions including the IL-1 gene cluster on chromosome

2 showed moderate evidence of linkage. The  $\lambda$  (LOCUS) value for the MHC was 4.5, suggesting that it accounted for around 34% of the familiarity of AS.

GWAS have rapidly supplanted linkage analysis in identifying genetic effects in AS, building on the work of the WTCCC in other polygenic diseases including RA. In AS, two major international consortia have been established for these studies with sufficient power to reliably identify genes increasing the risk of AS by around 5–10%. First, the Triple A (Australo-Anglo-American) Spondyloarthritis Consortium (TASC) and second, the International Genetics of AS (IGAS) consortium have generated samples of up to 13,000 cases for analysis. This has resulted in major genetic discoveries.

In 2007, TASC and WTCCC reported the results of a limited gene-targeted GWAS of 15,000 nonsynonymous single nucleotide polymorphisms (ns SNPs) in 1000 cases (103). The association with the MHC was confirmed (OR ~ 120,  $p < 10^{-120}$ ) as expected. Outside the MHC, the most striking association was with ERAP1, encoding the endoplasmic reticulum aminopeptidase 1 ( $p \sim 10^{-6}$ ), which was subsequently replicated in an independent data set. Numerous SNPs in ERAP1 were associated with AS; rs30187 encoding K528R was associated with an OR of 1.3 ( $p \sim 10^{-9}$ ). This association has been robustly replicated in several further studies (2,168–170), including a relatively large GWAS in Han Chinese ( $n = 3937$ ) in which the strongest association was also with rs30187 ( $p < 7 \times 10^{-4}$ ) (171). In this study, the other interesting observation was of weak association ( $p < 1.7 \times 10^{-3}$ ) with IL23R, encoding the IL23 receptor expressed by a subset of CD4 lymphocytes producing the cytokine IL17, known as T helper 17 (Th17) cells. IL23R is of particular interest because it is also associated with Crohn's disease and psoriasis, two conditions that are known to be overrepresented in patients with AS. This association was replicated in an independent data set and subsequently in an independent UK study and meta-analysis of previously published studies (168,170,172). The coding SNP rs11209026 is most strongly associated with AS (OR = 0.61,  $p < 10^{-10}$ ) as in Crohn's disease.

A subsequent GWAS reported by TASC in 2010 confirmed the association with the MHC, ERAP1 and IL23R but, in addition, identified several new associations (170). This study was more heavily powered than previous studies, comparing 2053 unrelated subjects with AS with 5140 ethnically matched controls. Cases were genotyped for 370,000 SNPs on the Illumina HumMap 370 genotyping platform and independent replication of positive results was undertaken in a further 898 cases and 1518 controls. Strong association was observed with two “gene deserts” on chromosomes 2p15 ( $p < 10^{-19}$ ) and 21q22 ( $p < 10^{-9}$ ) and also the genes ILIR2 (the decoy receptor for IL1) and ANTXR2 (encoding a receptor for anthrax toxin, but also functioning as a capillary growth factor). The region of chromosome 2p15 was again replicated in Han Chinese (171) with the marker rs10865331 most strongly associated ( $p = 2 \times 10^{-8}$ ).

Several major breakthroughs in our understanding of the genetic basis of AS have recently been made. These relate in particular to the likely role of ERAP1, the key role of the Th17 lymphocyte development pathway and the overlap between AS and other inflammatory disorders, including psoriasis and inflammatory bowel disease. In 2011, the TASC and WTCCC published the results of another large GWAS, in which a discovery set of 3023 cases of European ancestry were genotyped on the Illumina 660W-Quad microarray and compared with 8779 controls. A limited replication study of the top 50 “hits” was then undertaken in an independent set of 2111 cases and 4483 controls (2). The major findings are included in Figure 78-8. Of particular interest was the observation that the association with ERAP1 was limited to the B27-positive subset of patients, contrasting with the B27-negative minority (~9%) in whom no such association was apparent. Other associations, such as IL23R, were not influenced by HLA-B\*27 status of the patients. It is therefore clear that there is synergy between HLA-B\*27 and ERAP1 in susceptibility to AS. This most likely reflects a role for ERAP1 in trimming peptide antigens in the endoplasmic reticulum to optimal length (eight or nine amino acids) for binding to HLA class I molecules, including HLA-B27. The solution of

**FIGURE 78-8** Manhattan Plot showing association of AS with ERAP1 in (A) all patients, (B) B27-positive patients, and (C) B27-negative patients.

the crystal structure of ERAP1 at around the same time presented a structural basis for the understanding of this function of ERAP1. Furthermore, we were able to show that particular variants associated with protection against AS, such as K528R (rs30187), showed significantly reduced peptide processing characteristics (3). At least in theory, this would suggest that small molecule inhibitors of ERAP1 could be of value in the treatment or prevention of AS. The role of Th17 lymphocytes in AS is highlighted by the associations of a number of genes involved in this pathway (2,173). These include not only IL23R (expressed on Th17 lymphocytes) but also IL12B (encoding the common p40 chain of IL23 and IL12) and STAT3 (a key transcription factor for Th17 lymphocytes). Similar associations are seen in both psoriasis and inflammatory bowel disease, highlighting the shared genetic predisposition of these conditions (Chapters 150 and 68). Other associations include the transcription factor RUNX3, which is involved in lymphocyte differentiation, which is driven by IL-7. In this respect, it is interesting that we have also observed a moderate association with the IL-7 receptor ( $8 \times 10^{-5}$ ). The latest TASC/WTCCC study also shows a strong association with PTGER4 (prostaglandin E receptor 4), which is also associated with Crohn's disease. Prostaglandin E2 acts through this receptor to induce the production of IL23 and IL17, both of which are elevated in AS. Synovial levels of PTGER4 are increased in spondyloarthropathies. Of interest,  $\beta$ -glucan, a component of certain fungal and bacterial cell walls, induces PGE2 through interactions with components of the innate immune system, including CARD9 that is also associated with AS (174). This would be consistent with the hypothesis that AS might be induced by ubiquitous organisms carrying  $\beta$ -glucan by stimulation of the Th17 pathway. PTGER4 is also part of the anabolic bone response to stress. Its expression is increased in the synovium of those with spondyloarthropathies and this could potentially explain the new bone formation at sites of mechanical stress (entheses) in AS. These associations and doubtless many more will be further refined by the current IGAS consortium "ImmunoChip" experiment nearing completion in 2012. This will study known and candidate genes of inflammatory/immunological importance in 13,000 individuals globally and is likely to increase the number of target genes and pathways for study substantially.

**78.3.2.5 Management.** Pain relief and minimization of disability are the major aims of treatment. Physical exercises to maintain flexibility of the axial skeleton and good posture must be undertaken regularly, if necessary, under the supervision of a physiotherapist, since the benefit of intensive exercise regimens in hospital has been well recorded. Because of the likelihood of pronounced costovertebral joint involvement, lung function is often markedly reduced, and smoking should be strongly discouraged. Nonsteroidal anti-inflammatory drugs (NSAIDs) are usually highly effective although there is

only very weak evidence to suggest that they have any effect on the underlying rate of paraspinal ossification. Continuous treatment may be more effective at preventing new bone formation than on-demand therapy (175). Sulfasalazine and methotrexate are valuable for patients with active peripheral joint involvement but have no discernable effect on the spinal disease. Likewise, corticosteroids administered systemically are usually ineffective for spinal disease. In contrast, local injection of corticosteroids may be very valuable for the management of peripheral joint synovitis and occasionally for costovertebral joint disease and sacroiliitis. Management of active axial inflammation refractory to NSAIDs has been revolutionized by the demonstration that anti-TNF agents are highly effective in this condition (176). Whether these expensive drugs also retard the progression of joint ankylosis is as yet unknown. Promising results were demonstrated in early trials of anti-IL17 therapy in active AS, but larger studies are awaited. Uveitis is common (up to 40%) and is usually responsive to topical corticosteroids and mydriatics. Osteoporosis is recognized as a relatively early complication of the condition and may contribute to spinal deformity if wedge fractures occur. Bone densitometry measurements in the lumbar spine may be misleading because of the presence of syndesmophytes, which may cause spuriously high values. Joint surgery, particularly hip and knee arthroplasty, may be required in about 10% of patients but is particularly likely in those with juvenile-onset disease. Finally, a range of aids for daily living may be required, ranging from prismatic spectacles to allow severely kyphotic individuals to see where they are going, through to adaptations to cars (particularly additional mirrors for all-around vision) and wheelchairs for those with extreme disability and handicap.

### 78.3.3 Reactive Arthritis (Previously Reiter Syndrome)

Classic reactive arthritis (previously Reiter syndrome) represents the triad of arthritis, conjunctivitis, and urethritis, developing after a triggering bacterial infection; however, incomplete forms of this triad are more common.

**78.3.3.1 Clinical Features.** Reactive arthritis usually develops between 1 and 3 weeks after a precipitating infection. The arthritis typically affects a few large lower limb joints asymmetrically. Diffuse swelling of fingers and toes, referred to as "sausage digits," is typical of reactive or psoriatic arthritis. Axial skeletal involvement (particularly sacroiliitis), affects up to 50% of those affected, particularly those who are HLA-B\*27 positive. Plantar fasciitis and Achilles tendonitis are common. Mild conjunctivitis commonly precedes the arthritis. Mucocutaneous involvement may include mouth ulcers, sterile urethritis, circinate balanitis, and keratoderma blennorrhagica (a rash resembling pustular psoriasis).

The illness can be very severe and associated with marked systemic features of fever, malaise, and weight loss. It runs a variable course depending on the nature of the triggering organism and host genetic factors. Many cases are extremely mild and last only a few days. For those with more sustained synovitis, the average duration is <5 months. About 15% proceed to chronic disease and about one quarter may develop recurrent episodes (177). Chronic arthritis is much more likely in patients who are HLA-B\*27 positive, 20% of whom may ultimately develop AS. Patients with concurrent human immunodeficiency virus (HIV) infection tend to develop more severe arthritis and are probably at greater risk of disease because of increased exposure to the relevant genital tract pathogens.

**78.3.3.2 Epidemiology and Etiology.** While environmental triggers and genetic susceptibility contribute to reactive arthritis, it is not known how these interact to cause arthritis. Between 68% and 85% of cases of reactive arthritis occur in B27-positive individuals, and, in epidemics of arthritogenic bacterial infections, approximately 20% of B27-positive individuals will develop reactive arthritis.

Although the triggering bacteria cannot be cultured from the affected joints, there is reasonable evidence for the presence of bacterial proteins and nucleic acid in the joints (178). Cellular immunity to triggering bacteria has been demonstrated among both CD4- and CD8-positive B27-restricted T cells (158). These T cells are of the helper T cell type 1 subset of lymphocytes (179), which are thought to protect against intracellular infection. This seems appropriate as most arthritogenic pathogens are intracellular organisms, and it is consistent with theories suggesting a primary role for persistence of bacterial fragments within joints as the cause of reactive arthritis. The occurrence of reactive arthritis in face of CD4 lymphocyte depletion in HIV infection suggests that these cells are not critical in the development of the illness, in contrast with the situation in RA (in which the disease often improves as the CD4 lymphocyte count falls). Other theories implicate B27 itself as the autoimmune target, due to either molecular mimicry or loss of tolerance resulting from chemical alteration of the molecule. Evidence that B27 may be associated with lesser protection against invasion by, and less-efficient clearance of, enteric bacteria provides a further possible explanation for B27-related arthritis.

**78.3.3.3 Management.** Pain relief from the musculoskeletal manifestations of reactive arthritis is the primary objective in non-persistent disease. Nonsteroidal anti-inflammatory drugs are commonly used but have only a moderate beneficial effect. Local steroid injections are appropriate for peripheral arthritis and enthesopathy and may need frequent repetition. Sulfasalazine, methotrexate, and azathioprine have demonstrated beneficial effects and are appropriate to use in cases in which a protracted or recurrent course seems likely. Anti-TNF therapy may be effective in refractory cases. In cases of

presumed urogenitally acquired reactive arthritis, appropriate cultures should be taken for *Chlamydia* and *Neisseria gonorrhoeae*, as well as syphilis and HIV serology. Short courses of antibiotics are appropriate to clear any triggering infection, but there is also some evidence that longer courses of antibiotics may improve the late outcome of the arthritis (180).

### 78.3.4 Enteropathic Arthritis

Arthritis may complicate up to 10% of cases of inflammatory bowel disease. It may affect the axial skeleton and/or peripheral joints and is approximately twice as common in Crohn's disease as in ulcerative colitis. Axial arthritis occurs in 10–15% of individuals with inflammatory bowel disease, but the association of sacroiliitis with HLA-B\*27 may be weaker (50–60%) in this group of patients than in those suffering from AS without inflammatory bowel disease or psoriasis (~95%). These figures are heavily dependent on the means of ascertainment. For example, using a UK database of patients with known AS, we found the prevalence of HLA-B\*27 to be 83% in those with spondylitis and bowel disease (181). It seems possible that limited sacroiliitis (frequently asymptomatic) may be relatively common in inflammatory bowel disease, but HLA-B\*27 increases the likelihood of developing more extensive axial disease.

Peripheral arthritis exists in two distinct clinical forms that are also immunologically distinct (182). Both forms occur about twice as commonly with Crohn disease as ulcerative colitis. The type 1 arthropathy (self-limiting, pauciarticular, and associated with flares of the bowel disease) is positively associated with HLA-B\*27, HLA-B\*35, and HLA-DRB1\*0103 but the type 2 arthropathy (polyarticular, symmetrical, persistent, and not related to activity of the bowel disease) is associated with HLA-B\*44 (183). In view of the fact that AS has a high frequency of subclinical ileitis (184), it is interesting that peripheral arthropathy may predate the onset of clinically apparent inflammatory bowel disease by months or occasionally years. In type 1 arthropathy, the knees and ankles are most frequently affected, whereas in type 2 arthropathy, the metacarpophalangeal joints, wrists, and knees are most commonly affected.

### 78.3.5 Psoriatic Arthritis

Arthritis associated with psoriasis exhibits a considerable variety of clinical patterns and was only distinguished as a separate entity relatively recently (185). The arthropathy ranges through forms resembling RA to classical SpA. The extent to which these different expressions of psoriatic arthritis are under genetic controls is debatable since they do not appear to breed true in families with psoriatic arthritis (186).

**78.3.5.1 Epidemiology.** Psoriasis itself occurs in 1–2% of whites with an equal gender frequency. Common

forms of arthritis may thus occur fortuitously with psoriasis, without there being any causal relationship. Psoriatic arthritis typically occurs in 7% of patients with psoriasis although frequencies of up to 42% have been reported in some series (187,188). Arthritis is particularly common where there is nail involvement, but it may predate the onset of skin lesions. Although it usually starts in the third or fourth decade, pediatric onset is also quite common (see Section 78.4).

**78.3.5.2 Pathogenesis.** Inappropriate activation of the immune system appears to underlie both the skin and joint disease of psoriasis. In the psoriatic epidermis, keratinocytes proliferate and mature rapidly, leading to deficient adhesion of corneocytes that causes the characteristic scales of the psoriatic skin plaques. Significant infiltration of both the skin and joint synovium by T cells suggests a role for specific antigen presentation. Exacerbation of the skin lesions by CD4 depletion and HIV and/or acquired immunodeficiency syndrome has been observed, while specific T-cell-targeted therapy (e.g. cyclosporin A) may be effective. Furthermore, the efficacy of T-cell-targeted biologic therapies (alefacept directed against CD2 and efalizumab against LFA-1) in around 50% of patients supports this concept although the latter has been withdrawn from the market over safety concerns. An important role for TNF $\alpha$  in skin and joint lesions is emphasized by the efficacy of anti-TNF biologics although this is a complex relationship as anti-TNF agents have also been reported to precipitate flares of skin disease.

In the synovial membrane, there is evidence of new blood vessel growth, and substantial increase in the amounts of transforming growth factor- $\beta$ , platelet-derived growth factor, vascular endothelial growth factor, and angiopoietins has been observed (189).

**78.3.5.3 Genetics.** The genetic basis of psoriasis is presented in detail in Chapter 150. The heritability of psoriatic arthritis is substantial with a recurrence risk among first degree relatives ( $\lambda_1 = 30$ –55) and siblings ( $\lambda_s = 30$ ) estimated to be at least threefold higher than in psoriasis (190,191). Evidence from linkage and association studies led to the designation of the major psoriasis and psoriatic arthritis susceptibility locus within the MHC as PSORS1 (MIM\*177900). It has been shown to be primarily associated with type 1 psoriasis (onset <40 years of age), as no association was found in patients with psoriatic arthritis and late-onset psoriasis (192). The precise location of the PSORS1 risk allele is debated and is difficult to establish because of the extensive linkage disequilibrium within the MHC region; possibilities include HLA-Cw\*0602 (193) and the SNP rs10484554\*T (194).

Several other HLA associations have been reported in the literature; however, dissecting the contribution to psoriatic arthritis risk from the contribution to psoriasis risk is complex. A recent study, including a significant cohort of psoriatic arthritis patients, analyzed HLA associations by logistic regression. Alleles specifically associated with arthritis independently of cutaneous disease

included HLA-B\*27, B\*08, and B\*38 (195). Subgroup analysis demonstrated association of HLA-C\*06 and HLA-B\*27 with peripheral arthritis. HLA-B\*27 was strongly associated with the development of sacroiliitis, and B\*08, B\*38, and B\*39 were also associated with spondyloarthritis (195). Sacroiliitis is a common finding in patients with psoriatic arthritis; our survey of 105 unselected hospital outpatients showed abnormalities on MRI in one-third, but these were frequently asymptomatic (196). In psoriatic spondyloarthritis, the association with HLA-B\*27 is less strong (50–60%) than in the idiopathic forms of AS (95%), and we postulate that it correlates with more severe forms of spinal involvement.

Non-HLA genes within the MHC region, which may contribute to psoriatic arthritis risk include MICA\*002 (197), and the TNF promoter polymorphisms TNF-238A and TNF-857T (190), although the evidence is contradictory (190,198). An exploratory GWAS and replication study identified a single nucleotide polymorphism (SNP) rs2395029, which confers psoriatic arthritis risk with a high OR (3.2). This SNP lies within the MHC class I gene HCP5 positioned between the MICA and MICB loci (194).

GWAS have demonstrated significant associations with non-MHC gene loci including IL23R, IL12B, TNIP1, and TRAF3IP2 (190,199). Significant associations have also been linked with regions on chromosome 4q27 containing the IL2 and IL21 genes, and to chromosome 15q21 (194). Suggestive associations that have not reached significance, although have been replicated, include IL13, IL21, NFKBIA, NFAIP3, NOS2, and FBXL19 (190). These associations hint at pathogenic mechanisms underlying PsA as they include genes encoding Th2 (IL13) and Th17 (IL12B, IL23R) cytokines and signaling pathways including multiple associations with NF- $\kappa$ B signaling (TNIP1, TRAF3IP2, NFKBIA, TNFAIP3, NOS2, FBXL19).

Children of affected fathers are more likely to develop psoriasis or psoriatic arthritis (16.2%) than children of affected mothers (8.3%) (200,201). Evidence for imprinting is supported by the association of psoriatic arthritis with a region on chromosome 16q, which only confers risk when conditioned on paternal inheritance (202). Prognostically, males with axial psoriatic arthritis are more severely affected than females, in the absence of any differences in HLA distribution (203). A higher risk of progressive or erosive arthritis is found in patients carrying HLA-B\*39, HLA-DRB1\*04, HLA-DQ3 without HLA-DR7, HLA-B\*27 plus HLA-DR7, or the AA variant of the IL4 SNP rs1805010, while patients with the combination HLA-Cw\*6 plus HLA-DRB1\*07 have a better prognosis (204).

Approximately 75% of the genetic risk of psoriatic arthritis remains unidentified and further studies are required to identify risk alleles with smaller effect sizes, or indeed rare genetic variants conferring high risk (199,204). The emerging field of epigenetics will help to

elucidate how heritable pathways affecting gene expression may influence clinical risk and disease phenotype.

**78.3.5.4 Clinical Manifestations.** Classically, psoriatic arthritis has been divided into five subsets depending on clinical and radiographic criteria: (i) “classical” psoriatic arthritis, confined to the distal interphalangeal joints of the hands and feet (5%); (ii) arthritis mutilans (5%); (iii) symmetrical polyarthritis, resembling RA (15%); (iv) asymmetrical oligoarthritis (70%); and (v) spondyloarthritis (5%) (205). Recent studies have demonstrated that the pattern of onset of peripheral arthritis does not predict outcome in most cases, supporting the development of classification criteria, in which all patients with peripheral arthritis are pooled together (206).

Dactylitis (sausage digits) is characteristic of reactive or psoriatic arthritis, occurring in more than one-third of patients. Achilles tendonitis and plantar fasciitis (both forms of enthesitis) are also common. Dystrophic nail changes, including pitting, ridging, discoloration, and onycholysis, are associated particularly with distal interphalangeal joint disease. Overall, approximately 80% of patients with psoriatic arthritis have nail changes, compared with only 20% of psoriatics without arthritis.

Psoriatic arthritis is often a benign illness, but severe joint damage is not uncommon. Patients may present with severe acute monoarthritis and marked constitutional symptoms, mimicking sepsis or reactive arthritis. Typically, an increasing number of joints become involved with time although there is little relationship between this and the severity of the skin disease. Arthritis mutilans, although rare, causes severe joint destruction and disability. Axial disease is common but highly variable and tends to cause less functional impairment than in idiopathic AS. Compared to the “pure” form of AS, psoriatic spondyloarthritis also tends to be less symmetrical; radiographs may show non-marginal origin of syndesmophytes (origin not from the anterolateral border of the vertebral end plate); radiographic changes may skip vertebral segments; atlantoaxial involvement is more common; and unilateral sacroiliitis is not unusual. In reality, these divisions into subgroups are somewhat arbitrary; of those patients with peripheral joint disease, probably one-third have evidence of axial disease on MRI, although this is commonly asymptomatic (196).

**78.3.5.5 Management.** Nonsteroidal anti-inflammatory drugs similar to those used in RA are helpful for the peripheral joint arthritis. Intra-articular corticosteroids can be useful in peripheral arthritis and enthesitis, but oral corticosteroids have been associated with severe flares of cutaneous disease on withdrawal and are therefore not widely used. Anti-TNF biologic agents are highly effective in both the peripheral and axial joint manifestations of the disease although etanercept is considerably less effective at treating the skin manifestations (207,208).

Slow-acting disease-modifying antirheumatic drugs, such as sulfasalazine, methotrexate, and leflunomide,

may be effective in some cases, but cyclosporin A, despite its proven efficacy in skin disease, is relatively ineffective on the joints. In contrast to their helpful effects in peripheral arthritis, these agents are generally ineffective for psoriatic spondylitis.

## 78.4 JUVENILE IDIOPATHIC ARTHRITIS

Historically, this has been a somewhat ill-defined entity, a situation exacerbated by the differences in nomenclature in Europe and North America. Until recently, the term juvenile chronic arthritis has been used in Europe, whereas in North America, these disorders were often called juvenile chronic RA (in contrast to the use of this term in Europe specifically for seropositive juvenile-onset RA). Further confusion may arise from the use of the eponymous term Still disease for juvenile idiopathic arthritis (JIA). In 1897, Sir George Frederick Still distinguished juvenile forms of arthritis from adult RA, commenting on the fever found in the systemic form. Subsequently, in 1959, Ansell and Bywaters distinguished these childhood forms on the basis of their mode of onset. Thereafter, in general, “Still disease” was reserved for the systemic onset form of the disease although it has also been sometimes loosely applied to juvenile arthritis overall. These problems of classification can make comparisons between studies difficult. It has also complicated analysis of the genetic component of these disorders since many studies have not adequately distinguished between the various forms.

Childhood arthropathy has many potential causes, and it is important to exclude sepsis and viral infection, in particular, before concluding that the child has JIA. A World Health Organization/International League Against Rheumatism report proposed a widely accepted classification based on clinical patterns of disease (209) that defines seven subtypes of JIA:

- Systemic onset (11%)
- Oligoarthritis and extended oligoarthritis (50%)
- RF-positive polyarthritis (3%)
- RF-negative polyarthritis (17%)
- Enthesitis-related arthritis (10%)
- Psoriatic arthritis (7%).

Specific diseases associated with joint inflammation, such as SLE, rheumatic fever, septic arthritis, and neoplasia, are excluded from this classification.

### 78.4.1 Systemic-Onset JIA (Still Disease)

Still disease is the form of childhood arthropathy that carries the most adverse prognosis, with a significant mortality of 10%. It is characterized by systemic features including quotidian fevers, evanescent rash, lymphadenopathy, hepatosplenomegaly, arthropathy, and polyserositis (210). These features, coupled with a pronounced neutrophilia ( $>13 \times 10^9/L$  in 75% or more of patients),

may suggest infection, particularly when systemic features predate the arthropathy, which may happen by weeks or months. Other causes of fever and serositis should be considered, such as familial Mediterranean fever, particularly in patients of the appropriate ethnic background. Other important differential diagnoses include infection and malignancy. The disease has been reported in most populations worldwide and affects the sexes equally. The age of onset is variable but is usually between 4 and 6 years. It can also occur in adults, in whom it frequently causes diagnostic problems, particularly if systemic features predominate.

While some patients exhibit complete remission within 2 years of onset and others have repeated cycles of activity, the majority follow a chronic course (211). Some of the systemic features, including the fever and malaise, may respond well to short-term nonsteroidal anti-inflammatory drugs. For patients with more severe disease or poor prognostic signs such as active fever and high physician's global score, the systemic features may require moderate- to high-dose corticosteroids (including intravenous methylprednisolone). Anti-IL1 biologic therapy (e.g. Anakinra) may also be indicated in these patients and is frequently dramatically effective (212).

Multiple intra-articular injections of corticosteroids can be very effective in managing mild joint disease, but in patients with persistent or severe polyarticular involvement, disease-modifying antirheumatic drugs may be necessary. Weekly methotrexate (either orally or subcutaneously) has proved particularly beneficial compared to other second-line antirheumatic agents (e.g. gold salts, D-penicillamine, sulfasalazine), which have, in general, been disappointing. For resistant articular disease, biologic therapies, including anti-TNF (213), but particularly anti-IL1 and anti-IL6 agents, may be effective (212).

## 78.4.2 Oligoarticular JIA

Oligoarticular JIA affects young girls at least six times more frequently than boys, with a peak incidence at under 3 years of age, although the disease may also present for the first time in teenage life. The prevalence is between 20 and 30 per 100,000 and most ethnic groups are affected (214). By definition, children with this form of JIA have four or fewer joints affected within the first 6 months of disease, although in as many as one-third, the disease may subsequently extend to polyarticular involvement (210).

**78.4.2.1 Clinical Features.** Constitutional symptoms are not prominent in contrast to Still disease. Although joint pain is usually an obvious feature, the presentation is sometimes less obvious. Thus, a parent may notice a swollen joint in the absence of symptoms or observe nonspecific features, such as poor behavior or cessation from walking. Almost two-thirds of patients have

only one joint involved, and more than 90% have no more than two joints involved, in the first 6 months. Those children who remain oligoarticular for 5 years are unlikely subsequently to develop more extensive disease.

Levels of acute-phase reactants, such as C-reactive protein, may be normal or only slightly risen. If there is marked elevation, a search for alternative explanations is merited. This group of patients is classically associated with the presence of antinuclear antibodies in the serum (40–75%), usually in low titer (<1:640). Positive antinuclear antibodies indicate a higher risk of developing chronic anterior uveitis, which is the most serious potential complication of early-onset oligoarticular JIA (215), although all children with JIA are at risk. It causes blindness in up to 10% of patients, but this is avoidable if the appropriate screening and treatment steps are exercised. Ocular disease affects up to 57% of patients with oligoarticular JIA, usually with anterior uveitis although isolated posterior disease rarely may be present. Only a few of those with iritis (5%) have polyarticular disease at onset. JIA-related uveitis is usually asymptomatic and the onset of ocular features may be delayed. Therefore, slit-lamp examination is mandatory in all patients at diagnosis and regularly for many years thereafter (Guidelines for Screening for Uveitis in Juvenile Idiopathic Arthritis (JIA), BSPAR and the RCPOphth 2006). The uveitis is chronic, lasting between 2 and 15 years, and most commonly affects both eyes.

The joint disease associated with oligoarticular JIA typically resolves within 5 years, but chronic arthritis may sometimes recur, even many years later. Those children whose arthropathy extends to become polyarticular (about 20% overall) account for the majority exhibiting significant functional handicap at 15 years.

**78.4.2.2 Management.** It is important to keep the joints as normal as possible while the arthropathy is in its active phase. This can usually be accomplished by the use of nonsteroidal anti-inflammatory drugs and intra-articular corticosteroids (best administered under general anesthetic in young patients). In general, there is a good response, and second-line drugs, such as methotrexate, are reserved for patients with persistent or severe disease. Physical methods of treatment to prevent contracture and preserve muscle strength are beneficial. Surgery is rarely needed except in those cases in which severe contractures develop or abnormalities of bone growth occur secondary to epiphyseal involvement. Anti-TNF biologics are potentially very effective in resistant cases. Topical corticosteroids and mydriatics are effective in 40% of patients with uveitis, but intraocular steroids or systemic corticosteroids are frequently required to prevent the formation of posterior synechiae between the lens and the iris. In some cases, immunosuppressive drugs such as azathioprine, chlorambucil, and cyclosporin A may be necessary to control the uveitis. The ocular disease is

potentially sight-threatening and demands regular ophthalmologic review.

### 78.4.3 Polyarticular JIA

Polyarticular JIA is much less clearly defined than the oligoarticular and systemic-onset forms. It is apparent that some patients whose disease begins with limited joint involvement subsequently progress to a more widespread form of arthropathy with a correspondingly poorer outcome (these patients are included under the extended oligoarticular disease subset). If this occurs, it is invariably within the first 5 years of disease. Other patients have polyarticular symptoms from the outset, but these appear to represent a relatively heterogeneous group with the exception of the subgroup with juvenile-onset seropositive RA (3% of all JIA). The prognosis of this specific subset is similar to the adult form of RA, with similar immunogenetic associations. Indeed, the HLA associations are even more striking in the juvenile form of the disease, and the association with the HLA-DRB1\*0401/\*0404 genotype is particularly striking (33).

### 78.4.4 Genetics of JIA

It has been estimated that JIA has a prevalence of between 20 and 120 per 100,000 and an annual incidence of 10–20 per 100,000. The prevalence appears to be similar in Europe and North America in general although a threefold excess risk to Native American children compared with their white counterparts in British Columbia has been reported. No differences have been observed in the prevalence in North American black and white children, but, by contrast, the condition appears to be rare in China. The available family studies provide support for a genetic component to JIA, but many of these studies predate the more accurate classification of JIA into various subgroups. Thus, Lawrence (216) found an excess concordance in monozygotic twins (40%) versus dizygotic twins (9%), but these studies included only 16 twin pairs. Subsequently Moroldo et al. (217) studied 71 sib-pairs affected by juvenile chronic arthritis and found substantial concordance (70–80%) for the type of disease between the sibs. There is a slight excess recurrence in sibs for systemic-onset JIA, and a genetic component to the disease arising from HLA-linked genes has been suggested although these results are inconsistent.

HLA-DR alleles have been estimated to confer almost 20% of the total sibling recurrence risk in JIA (218) although the risks associated with HLA alleles differ between the JIA subtypes. HLA-DRB1\*08 (a rare allele in most white populations) is consistently found in between 25% and 50% of patients with oligoarticular JIA (relative risk ~12). HLA-DRB1\*11 (relative risk ~5) is also increased, and some studies have suggested a weak association with HLA-DRB1\*13. Our results suggest that

HLA-DRB1\*13 is most closely associated with the presence of uveitis (OR 3.4) in oligoarticular disease (219). HLA-DRB1\*04, which is associated with RA in adults is associated with juvenile seropositive polyarthritis (OR 3.2), but is protective against many other JIA subtypes (220). DRB1\*07 is associated with decreased risk of JIA (220). There is considerable evidence for a marked compound heterozygote effect with predisposing DRB1 alleles (e.g. HLA-DRB1\*08/DRB1\*11) (221–223), analogous to the situation in RA with DRB1\*0401/\*0404 (see Section 78.2.5). Gender has a significant influence on the age that the HLA risk is conferred (224). HLA analysis has been particularly useful in distinguishing a subset of children with pauciarticular disease, typically boys older than 9 years, in whom limited joint involvement with an associated enthesopathy is the first sign of spondyloarthritis (see Section 78.3.2). This variant is strongly associated with HLA-B\*27 and is known to be associated with an excess of family members with sacroiliitis. Many of these children go on to develop AS although others appear to continue with a more peripheral form of enthesopathy without AS.

Other HLA alleles also contribute to risk. HLA-DQA1\*0103 is associated with oligoarticular disease and HLA-DQA1\*05 with oligoarticular and systemic-onset arthritis. HLA-DQA1\*02 is protective against oligoarticular and seropositive polyarthritis (220). DPB1\*0201 confers risk of early-onset arthritis (221). Previously reported HLA-DRB1/DQB1 risk associations were found to be solely due to the effect of the DRB1 locus (221).

It has been suggested that particular combinations of HLA-A\*2, DPB1\*0201, and other DRB1 susceptibility alleles (\*08, \*11, \*13) are associated with onset of oligoarticular disease under 3 years of age (224). The DRB1\*1501–DQA1\*0102–DQB1\*0602 haplotype protects against oligo- and polyarticular JIA (221).

Conducting studies of sufficient power to examine the risk contribution of non-HLA alleles is made difficult by the rarity of JIA and the phenotypic heterogeneity of the disease. While studies encompassing JIA as an umbrella disease may mask genetic associations with individual JIA subsets, subset subanalysis may fail to detect genetic risk alleles with small effects (225). Therefore, approaches to identifying candidate genes have included investigating loci associated with other autoimmune diseases (226).

More than 100 non-MHC risk alleles have been examined (225), and although many were found to be positively associated, only a small number of these have been replicated to date. The PTPN22 and IL2RA gene associations have reached genome-wide significance. PTPN22 is involved with T-cell signaling and confers risk of oligo- and polyarticular arthritis, while IL2RA, which codes for the high-affinity IL2 receptor alpha chain, is particularly associated with ANA positivity, female gender, and oligoarthritis (227,228). Other significant associations

include genes implicated in T-cell signaling and activation (STAT4, VTCN1), innate immunity (TNFA, TNFAIP3, TRAF1/C5, MIF, SCL11A1) and cartilage homeostasis (WISP3). Many of these genes are associated with risk of other autoimmune conditions such as RA (229). For example, the ERAP1 and IL23R gene variants, which are associated with AS in adults, have been found to increase risk of enthesitis-related arthritis (230) and juvenile psoriatic arthritis, respectively. These findings await replication (230).

The strong association of oligo- and polyarticular JIA with HLA class II alleles suggests pathogenic involvement of CD4 T cells (227). No etiologic agents have yet been identified in this disorder although autoantigens present in the eyes and the joints are strongly suggested as being responsible for the chronic inflammatory process in oligoarticular disease. The non-HLA associations implicate Tregs, which may influence the balance between pro- and anti-inflammatory processes, as well as innate immune cells, which may contribute to cytokine production and CD4 T-cell activation. The distinct HLA and non-HLA genetic association between the JIA subsets implies differences in pathogenic mechanisms (227).

## Amyloidosis and Other Protein Deposition Diseases

*Merrill D Benson*

Professor of Pathology and Laboratory Medicine, Professor of Medical and Molecular Genetics, and Professor of Medicine, Indiana University School of Medicine, Indianapolis, IN, USA

### 79.1 INTRODUCTION

Amyloidosis is the classic example of protein deposition disease. However, there are many forms of amyloidosis and, by definition, these represent only those diseases associated with extracellular deposits of  $\beta$ -structured protein fibrils (1–4). We now know that there are diseases characterized by protein deposits that may be extracellular or intracellular, and the deposits may contain either fibrillar or nonfibrillar protein aggregates.

Each type of protein deposition disease, whether fibrillar or nonfibrillar, is characterized by a specific protein that forms the major constituent of the pathologic deposits. In the case of the amyloidoses, there are at least 26 proteins that can form extracellular  $\beta$ -structured fibril deposits, and each represents a separate disease entity (5). Some of these diseases are systemic (involving several organ systems) and some are localized (limited to one organ). The systemic forms of amyloidosis may be sporadic or acquired (e.g. immunoglobulin AL amyloidosis); secondary to other conditions (e.g. reactive AA amyloidosis) or hereditary (e.g. familial amyloidotic polyneuropathy (FAP)/transthyretin (TTR) amyloidosis). The localized forms of amyloidosis may also be sporadic or acquired (e.g. AL amyloid in the upper respiratory tract, urinary tract or plasmacytomas and, most important, Alzheimer disease); secondary to other conditions (e.g. infectious Creutzfeldt–Jakob disease) or hereditary (e.g. many of the corneal dystrophies, familial Alzheimer disease, Gerstmann–Sträussler–Scheinker pri-onosis). Amyloid deposits composed of several specific proteins can produce systemic or localized, sporadic or secondary, and hereditary or nonhereditary pathologic conditions. Each of these diseases probably shares certain pathogenic mechanisms that lead to  $\beta$ -fibril formation but there must also be specific factors that dictate where, when and how amyloid deposits occur in each of these disease entities. A similar story can be constructed for the non-fibrillary protein deposition conditions, which have

only recently come to attention. These include systemic immunoglobulin light chain deposition disease and the localized, mainly intracellular, protein deposits such as  $\alpha$ -synuclein (Lewy bodies), tau (Pick bodies), huntingtin and neuroserpin. All of these protein deposits are associated with one or more disease entities. However, they do not form the  $\beta$ -structured fibrils that we call amyloid.

In this chapter, we are concerned with those forms of amyloidosis and other protein deposition diseases that give hereditary syndromes. First, however, we should consider the more common types of amyloidosis because they can tell us much about the mechanisms of fibrillogenesis, and they often must be included in the differential diagnosis of hereditary amyloidosis.

Immunoglobulin light chain (LC) amyloidosis (AL) is the most common type of amyloidosis (6). It is a sporadic (acquired) disease that increases in incidence with age. It has no definite hereditary features other than increased incidence in families with a history of multiple myeloma. AL amyloidosis is a monoclonal plasma cell disease in which proteolysed fragments of immunoglobulin LC protein ( $\kappa$  or  $\lambda$ ) are deposited as  $\beta$ -structured fibrils (7). These deposits are extracellular and occur in major organs such as kidney, heart, liver and spleen, and also in the blood vessel walls of most organs. This is the most aggressive form of amyloidosis, with median 1-year survival after diagnosis of approximately 18 months for nontreated patients, 5-year survival of 20%, and 10-year survival of only 5% (8). It may cause carpal tunnel syndrome and sensorimotor polyneuropathy, and, therefore, is often mistaken for TTR amyloidosis (FAP). The cardiomyopathy of some forms of hereditary apolipoprotein A-I (apo A-I) amyloidosis may also be mistaken for AL amyloidosis. The prognosis is markedly different.

Much is known about the pathogenesis of AL amyloidosis, and this is significant for the consideration of amyloid fibrillogenesis in general. For example, X-ray diffraction analysis has shown the high degree of  $\beta$ -pleated

sheet structure in the immunoglobulin LC domains (9). This would be expected to be an important factor in fibrillogenesis. However, the greater incidence of  $\lambda$  LC amyloidosis than  $\kappa$  LC amyloidosis suggests that there are more cryptic structural factors that influence fibrillogenesis than just the overall  $\beta$  structure that is shared by both  $\kappa$  and  $\lambda$  light chains. The selective deposition as fibrils of one specific monoclonal light chain in the presence of a plethora of polyclonal immunoglobulins also testifies to the importance of structure in fibrillogenesis. There is tremendous interest in the physical properties of peptides that contribute to  $\beta$  structure and fibril formation (10). However, it should be remembered that, while structure of a peptide may be the basis for amyloid fibril formation, there must be specific *in vivo* metabolic processes that lead to the end result.

Reactive (secondary) AA amyloidosis appears to be much less common than it used to be. This may be the result of improved treatment of the infections (tuberculosis) and inflammatory (rheumatoid arthritis) diseases that predispose to this form of amyloidosis. Research on AA amyloidosis has shown that increased synthesis of the fibril precursor protein, serum amyloid A (SAA) and certain tissue factors (amyloid-enhancing factor) are important for fibrillogenesis (11). The primary structure of the precursor protein is also important and, in the case of inbred mice, explains the species specificity of amyloid fibril formation (12). Of particular interest to the geneticist is the AA amyloidosis associated with autosomal recessive febrile illnesses, such as familial Mediterranean fever (FMF) (13), and autosomal dominant febrile syndromes, such as TRAPS (tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) receptor-associated periodic syndromes) (14), Muckle-Wells syndrome (15) and familial cold urticaria (16). The amyloidosis is not inherited: it is a reactive form of amyloidosis, a result of chronic overproduction of the amyloid precursor protein SAA. The fact that different mutations in the FMF gene (MeV) (17,18), in the TNF- $\alpha$  receptor gene (19), and in the CIAS1 gene (20) result in varying degrees of amyloid induction points to other, unknown factors in fibrillogenesis.

## 79.2 HEREDITARY SYSTEMIC AMYLOIDOSIS

### 79.2.1 Transthyretin Amyloidosis

First and foremost among the genetically determined forms of amyloidosis and other protein deposition diseases are the TTR amyloidoses (21) (Table 79-1). This condition was originally named FAP by Andrade, who in 1952 first described this peculiar syndrome of sensorimotor neuropathy with varying degrees of organ involvement (heart, kidney, eye) (22). This form of amyloidosis is now known to be the most widespread and prevalent of the hereditary amyloidoses. It is transmitted as an autosomal dominant trait owing to mutations in the plasma protein TTR (formerly named prealbumin) (23). There are more

than 100 mutations in TTR known to cause the disease, and all are single amino acid substitutions except one, which is loss of one amino acid residue ( $\Delta$ Val122) (21).

TTR is a plasma transport protein for thyroxine and retinol-binding protein/vitamin A (24). It is synthesized in the liver as a single polypeptide chain of 127 amino acid residues (25,26). The gene has been localized to 18q23 (27,28). A murine gene knockout model shows that TTR is not essential for life, although expression in embryos and adults suggests that it is normally important in both fetal development and adult life (29).

Mutations in TTR presumably alter the molecular structure, and this leads to aberrant degradation and aggregation of the protein as amyloid fibrils (Figure 79-1). TTR has extensive  $\beta$ -pleated sheet structure, and this makes it a good candidate for fibril formation (30). Indeed, TTR amyloid fibril deposits are commonly found in the hearts of aged humans who do not have any mutant form of the protein (31,32). It seems logical, therefore, that mutations in TTR are not necessary for amyloidosis but, instead, move the age of onset to earlier in adult life. TTR amyloidosis is an adult-onset disease in which the genetic mutation has been passed on to the next generation before serious clinical disease presents itself.

Clinically, TTR amyloidosis usually starts as a small fiber peripheral neuropathy affecting the extremities and autonomic functions (22,33–35). It often presents as paresthesias or dysesthesia in the lower limbs but may start as carpal tunnel syndrome, alternating diarrhea and constipation, impotence in males, restrictive cardiomyopathy or, in rare forms, central nervous system (CNS) syndromes due to leptomeningeal amyloid infiltration (36–38). Vitreous opacities due to amyloid fibril deposition are seen in one-quarter to one-third of kindreds with mutant forms of TTR (21,39) (Figure 79-2). In fact, the presence of vitreous amyloid in a patient essentially limits the diagnosis to some form of TTR amyloidosis. Progression of the neuropathy is cephalad and may lead to sensory neuropathy over much of the body, plus loss of motor function that precludes ambulation. Even paralysis of the recurrent laryngeal nerve has been seen with this type of amyloidosis. Death used to be the result of infection and inanition in many persons affected with FAP. Now, restrictive cardiomyopathy and those syndromes associated with seriously compromised cardiac function (e.g. renal failure) are the most common cause of demise.

Disease onset varies from the third decade of life to advanced age, with examples of incomplete penetrance in a number of kindreds with different TTR mutations (40,41). In general, it would seem that the disease is more rapidly progressive in individuals affected at an early age, with time from diagnosis to death being less than a decade. In older-onset syndromes (past age 50), it is not unusual to observe periods from diagnosis to death of 15–20 years. In these cases, the disease usually involves slowly progressive restrictive cardiomyopathy and lesser degrees of peripheral neuropathy.

TABLE 79-1 TTR Amyloidoses

Mutation	Clinical Features <sup>a</sup>	Geographic Kindreds
Cys10Arg	Heart, eye, PN	United States (PA)
Leu12Pro	LM	United Kingdom
Val14Leu	PN	Italy
Asp18Glu	PN	South America, United States

<sup>a</sup>AN, autonomic neuropathy; CTS, carpal tunnel syndrome; LM, leptomeningeal; PN, peripheral neuropathy.

The Val30Met form of TTR amyloidosis is the most common type of FAP. It was originally described in patients in northern Portugal, but has been found in kindreds in northern Sweden, Japan, Cypress, Turkey and Greece, and, of course, in many American families of European descent (22,33,41–43). Haplotype analysis

has shown that the Portuguese, the Swedish and many of the Japanese kindreds probably have the mutant gene that originated in northern Portugal (44). Similar studies reveal that some English, Turkish and Japanese kindreds probably have the Val30Met gene from other mutation events (45).

Other widespread forms of TTR amyloidosis include the Thr60Ala mutation, which was first discovered in a large kindred in the Appalachian region of the United States (46,47) but now has been shown to have originated in Ireland (48). There are kindreds of Irish ancestry with this mutation in Australia and New Zealand. The TTR Leu58His mutation was discovered in a number of kindreds in the eastern United States (Maryland and Pennsylvania) (34,49). It has now been found in Germany in the birthplace of the ancestors of the American kindreds (50). Both the Thr60Ala and Leu58His mutations are associated with relatively late-onset disease with progressive cardiomyopathy.

The Ser77Tyr TTR amyloidosis has also been found in many countries, including the United States, Germany and France (51,52). Haplotype studies indicate that a French kindred probably had a separate mutation event (53). Other TTR amyloidosis kindreds are relatively restricted geographically. The Indiana/Swiss Ile84Ser amyloidosis is present in mid-America, Switzerland and one kindred in Hungary (35,39,54,55). The Cys10Arg mutation has been found in one kindred in the United States (56). The  $\Delta$ Val122 TTR mutation, which was discovered in an Ecuadorian family, has now been found in Spain, perhaps indicating the country of origin (57).

Perhaps the greatest number of carriers of a TTR mutation that causes amyloidosis is represented by the Val122Ile mutation, which is present in 3–4% of African Americans (58–60). This mutation, which has

**FIGURE 79-1** Amyloid deposits in the myocardium stain with Congo red (A) and give characteristic green birefringence when viewed by polarization microscopy (B).

**FIGURE 79-2** Amyloid in the vitreous of the eye, which causes progressive loss of vision, can be seen as fluffy deposits on funduscopy examination.

now been discovered in those parts of western Africa from which most American blacks originated, causes restrictive cardiomyopathy in later adult life, usually after the age 60. There is often minor associated neuropathy, and the disease is frequently not recognized clinically. Instead, the patient is often thought to have heart failure due to previous hypertensive or coronary vascular disease.

**79.2.1.1 Clinical Variations in FAP.** Although the TTR amyloidoses are all systemic diseases, the marked variation in organ system involvement leads to syndromes that obscure the underlying diagnosis (this is particularly true for certain mutations in TTR that are associated with relatively similar clinical presentations). The classic perception of FAP is of a syndrome of sensorimotor and autonomic neuropathy with malfunction of the gastrointestinal tract, orthostatic hypotension, varying degrees of restrictive cardiomyopathy and nephropathy. This clinical presentation is typical of the Portuguese FAP, Val30Met (22), as well as Ser77Tyr (61) and a majority of the other mutations. In early studies, it was recognized that certain mutations resulted in disease with the initial presentation of carpal tunnel syndrome (FAP II), which is characteristic of the Leu58His mutation in the Maryland kindreds (34) and the Ile84Ser mutation in the Indiana kindred (35). It has now been appreciated that peripheral neuropathy may be a minor aspect of the amyloidosis. This is particularly true of the Thr60Ala (46), Ile68Leu (62), Ile84Ser (35), Ile84Asn (63), Ala97Gly (64), Ile107Val (65) and Val122Ile (58,60) mutations. The Leu111Met mutation originally described by Frederiksen and colleagues (66) in Denmark is present in a kindred with restrictive cardiomyopathy and no signs of peripheral neuropathy (67). Of particular interest are those TTR mutations that cause extensive leptomeningeal vascular amyloid deposition—Leu12Pro, Asp18Gly (38), Val30Gly (36,37) and Phe64Ser (68,69)—and are associated with intracranial hemorrhage, either subarachnoid or intracerebral. In the case of two of these mutations (Asp18Gly and Val30Gly), neurodegeneration with dementia is a prominent feature of the syndrome (36,38). Other clinical variations have been seen. In one kindred with Tyr69His only vitreous amyloid was seen (70), whereas in another Tyr69His kindred, patients suffer with the consequences of leptomeningeal amyloidosis, and a Japanese kindred (Tyr114His) had only carpal tunnel syndrome as evidence of amyloidosis (71). Thus, although multi-organ involvement with TTR amyloidosis may produce syndromes that are relatively easy to diagnose, the many variations in clinical presentation obviously make this group of diseases underappreciated.

**79.2.1.2 Genetics.** The TTR amyloidoses show an autosomal dominant inheritance. Most affected individuals are heterozygous for a point mutation, indicating that the disease is the result of “gain of function.” This gain of function, however, would appear only to

be the ability of the mutant TTR to participate in the synthesis of amyloid fibrils. A few TTR mutations have been found in the homozygous state. Homozygosity for TTR Val30Met is associated with clinical disease that is not distinguished from that seen in heterozygotes (40). The same would appear to be true for the Val122Ile TTR mutation, which is typically expressed as restrictive cardiomyopathy in African Americans after the age 60 (60,72). Homozygosity for TTR Leu58His, however, has been reported to give earlier onset and more aggressive disease (73). Studies have suggested that inheritance of the mutant Val30Met gene from an affected mother results in earlier onset than inheritance from an affected father (74). Reduced penetrance of TTR amyloidosis is a confounding factor in diagnosis, and has often resulted in a misdiagnosis of immunoglobulin amyloidosis, in which peripheral neuropathy and cardiomyopathy are often seen. Reduced penetrance is particularly high in the northern Sweden population with TTR Val30Met (40,41) but is also seen in the United States with the same mutation, with the Thr60Ala and Cys10Arg mutations, and with several other mutations (56). On the other hand, extensive study of the Indiana/Swiss kindred with Ile84Ser has not identified an escapee over several generations (75).

TTR mutations associated with amyloidosis have been found in most countries of the world (see Table 79-1). Although larger representations of mutations have been from a few countries, including Italy, Germany, Japan, France and the United States, this is probably largely a reflection of scientific interest and medical sophistication in these countries. Over the last 20 years in which the disease has been studied at the molecular biology level, all of the mutations that have been discovered in the United States have been traced to immigrant populations. To date, no TTR mutation has been found in a Native American. No TTR mutation associated with amyloidosis has been found in Australian Aborigines or in Polynesians, and only the Val122Ile mutation has been described in individuals from Africa. This will undoubtedly change with the advancement and availability of DNA diagnostics. Several of the TTR mutations found in the United States have been traced to ancestors in Europe: the Leu58His TTR to Germany (50), the Val30Met to Portugal and Sweden (76), the Thr60Ala to Ireland (48) and the Ser77Tyr to Germany. The ΔVal122 TTR, originally discovered in a kindred in Ecuador, has now been reported from Spain (57).

Haplotype analysis based on polymorphisms in TTR have produced convincing evidence that the Val30Met mutation of the Portuguese was shared with the people of northern Sweden and with a number of kindreds in Japan; however, haplotype analysis indicates that at least two other mutation events occurred to produce the Val30Met mutation in English, Turkish and Japanese

families (44,45,77). There are several CpG dinucleotide sequences in TTR, which may explain the increased incidence of some TTR mutations, including Val30Met and Val122Ile (44). However, the large number of TTR mutations that have been discovered, and the fact that some mutations, such as Ser77Tyr, are seen on more than one haplotype and would not be predicted to have an increased mutation rate, indicate a high rate of retention of spontaneous mutations. Factors that might add to this observation include the following:

1. TTR amyloidosis is an adult-onset disease and appears to have minimal effect on procreation.
2. TTR, as shown by the murine knockout model, appears not to be necessary for survival and normal development (29).
3. Any loss of function by TTR mutation, such as reduced thyroxine binding or vitamin A transport, is compensated for by other biologic systems.
4. The identification of many TTR mutations may be enhanced by the fact that almost any alteration in structure of this heavily  $\beta$ -structured molecule will lead to abnormal metabolism and amyloid formation. There are only 12 reported mutations in TTR that have not been associated with the development of amyloidosis, whereas over 100 mutations can cause disease (21).

## 79.2.2 Other Systemic Amyloidoses

**79.2.2.1 Apolipoprotein A-I Amyloidosis.** Apo A-I amyloidosis was originally designated FAP III (78). Although the first kindred with this type of amyloidosis had a clinical syndrome that included peripheral neuropathy and renal failure, the presence of hepatic amyloidosis and gastric ulcers in a large number of affected individuals indicated that it was different from FAP I and FAP II, which were subsequently shown to be related to mutations in TTR. This disparity was confirmed by the demonstration that the amyloid in FAP III was the result of a mutation in apo A-I in which an arginine was substituted for glycine at position 26 of the mature protein (79). Subsequently, a number of mutations in apo A-I have been identified that are associated with systemic amyloidosis (80–85). Most are single nucleotide point mutations, but single nucleotide deletions with shift of reading frame and codon insertions have also been reported (Table 79-2). This is an autosomal dominant disease, with all affected individuals being heterozygous; however, the small numbers of kindreds with this disease have precluded an assessment of degree of penetrance. The gene for apo A-I is on chromosome 11 and codes for a mature protein of 243 amino acid residues that is the major protein constituent of plasma high-density lipoprotein. Amyloid deposits contain only the first 83 to 93 N-terminal residues of apo A-I and, as native apo A-I has been shown to have a predominantly

$\alpha$ -helical structure, major rearrangement of the amino-terminal peptide must occur during catabolic processing so that  $\beta$ -pleated sheet amyloid fibrils are formed (86). One study has shown increased catabolism of mutant apo A-I Gly26Arg, and this may be a significant factor in the pathogenesis of the amyloidosis (87). The first mutations in apo A-I associated with amyloidosis were found in the amino-terminal portion of the protein, the portion that forms amyloid fibrils. The clinical syndrome usually involves renal and hepatic amyloidosis. Only the Gly26Arg mutation is associated with neuropathy, and this has not been found in all kindreds with this mutation. Subsequently, mutations in the carboxyl-terminal portion of apo A-I were discovered and were shown to cause a different syndrome characterized more by cardiac, dermal and laryngeal amyloid deposition (Figure 79-3) (88–92). These mutations indicate that incorporation into the amyloid fibril is not required to cause amyloid formation, and, indeed, alteration in metabolism is probably a major factor in pathogenesis.

**79.2.2.2 Gelsolin-Related Amyloidosis.** FAP IV was the designation given to the Finnish type of amyloidosis originally reported by Meretoja (93,94). It is an adult-onset disease with lattice corneal dystrophy occurring as early as the second decade of life, followed by neuropathy of the cranial nerves, thickening and later laxity of facial skin, and a mild sensory neuropathy in the limbs (95). It is a systemic disease with deposits of amyloid also occurring in the heart and gastrointestinal tract. Analysis of the deposits has shown that the fibril protein is a 71-amino acid residue internal fragment of gelsolin. The disease in the original Finnish kindreds has been shown to be related to the substitution of asparagine for aspartic acid at position 187 of the mature protein (96–98). The disease has now been reported in American families, in The Netherlands and in Japan (99,100). Most affected individuals are heterozygous for the Asp187Asn mutation, but a few homozygous individuals have been identified. A separate mutation at the same codon of gelsolin (Asp187Tyr) has been found in kindreds from Denmark and Czechoslovakia with similar syndromes (Table 79-2) (99).

Gelsolin is a calcium-binding protein that is involved in the fragmentation of actin filaments (101,102). It is coded by a single gene on chromosome 9 (9q32–q34), with two forms resulting from alternative splicing (101). Cytoplasmic gelsolin has an important role in cytoskeletal reorganization, whereas plasma gelsolin binds actin and presumably functions to clear actin from the plasma. It is the plasma protein that is most likely the precursor of amyloid fibrils. In general, gelsolin amyloidosis is not associated with shortened longevity, although homozygosity for the Asp187Asn mutation is associated with severe renal disease (103). The lattice corneal dystrophy is often not of great clinical significance and, if necessary, may be treated with corneal transplantation.

<sup>a</sup>PN, peripheral neuropathy.<sup>b</sup>(fs), frame shift.**FIGURE 79-3** Apolipoprotein A-I amyloid deposits in the skin are characteristic of the Leu90Pro and Arg173Pro mutations.

**79.2.2.3 Lysozyme Amyloidosis.** Six mutations in lysozyme have been shown to cause systemic amyloidosis (Table 79-2) (52,104,105). In one family, a petechial skin rash was a presenting feature, with subsequent renal failure (Ile56Thr) and in another petechial skin rash was associated with cardiomyopathy (Tyr54Asn). Other mutations—Asp67His, Trp64Arg, Phe57Ile and Trp112Arg—are also associated with renal amyloidosis. Lysozyme is a bacteriolytic enzyme that is synthesized by polymorphonuclear leukocytes and macrophages. The gene on chromosome 12 codes for a 14,500-Da protein. The entire mature protein is incorporated into amyloid fibrils, but only the mutant form has been found in all tissues examined, which have been from heterozygous individuals (106).

**79.2.2.4 Cystatin C Amyloidosis (Hereditary Cerebral Hemorrhage with Amyloidosis).** A mutant form of cystatin C, a serine protease inhibitor, has been shown to cause leptomeningeal vascular amyloidosis, which is associated with repeated intracranial hemorrhage (107). The disease is systemic, with amyloid deposits in other organs such as the spleen. It is found principally in Iceland, is autosomal dominant, and usually occurs in the third or fourth decade of life. The amyloid deposits are composed of cystatin C lacking the first 10 amino acids of the mature protein (108). A substitution of glutamine for leucine at position 58 of the amyloid subunit peptide determines the expression of the disease (109). The gene for cystatin C is on chromosome 20 (110).

**79.2.2.5 Fibrinogen A $\alpha$  Chain Amyloidosis.** Nine mutations in the gene for fibrinogen A $\alpha$  chain have been found to be associated with amyloidosis expressed as nephropathy (Table 79-2) (111,112). Five are point mutations that give single amino acid substitutions, and two are single nucleotide deletions that cause a shift in the reading frame of the messenger RNA and aberrant peptides with premature termination (113,114). A recently described deletion/insertion mutation associated with renal amyloidosis in a pediatric patient appears to have occurred de novo. All mutations are in the protease-sensitive carboxyl-terminal portion of the A $\alpha$  chain and result in proteolytic peptides containing from 49 to 83 amino acid residues (115). The clinical syndrome is characteristic, with the development of hypertension followed by proteinuria and then progressive azotemia. Life can be prolonged for several years by dialysis, but hepatic and splenic involvement will occur. Renal transplantation has been shown to be followed by amyloid deposition in the transplanted organ within 1 to 10 years. Families in the United States, Canada and Germany have been described with these mutations. The gene for fibrinogen A $\alpha$  chain is on chromosome 4 and codes for a mature protein with a molecular weight of 66,000 Da (116). Fibrinogen is synthesized exclusively by the liver and demonstrates a modest acute-phase response to injury.

**79.2.2.6 Apolipoprotein A-II Amyloidosis.** In 1973, Weiss and Page (117) described the autopsy pathology of two sisters with renal amyloidosis. Subsequent study of affected offspring revealed that the amyloid was composed of Apo A-II that was 21 amino acid residues longer than the wild-type protein, the result of mutation in the A-II stop codon (Stop76Gly) (118). The clinical syndrome is characterized by hypertension followed by slowly progressive renal failure. Other stop mutations (Stop76Ser, Stop76Arg, Stop76Leu) have now been described in families with similar clinical disease (119,120).

## 79.2.3 Diagnosis

The diagnosis of systemic hereditary amyloidosis is rarely made in a timely fashion. The systemic amyloidoses can give a number of symptom complexes (congestive

**FIGURE 79-4** Amyloid deposits within peripheral nerves (arrows) are often not evenly distributed and may be missed on standard nerve biopsy. Amyloid in the walls of perineural blood vessels (arrowhead) may reveal the diagnosis.

heart failure, renal failure, polyneuropathy, diarrhea) that reflect the clinical presentation of several more common and mundane diseases. Therefore, a heightened awareness of the various forms of hereditary amyloidosis is very important to early diagnosis and institution of appropriate therapies. There are a number of features of hereditary amyloidosis that should raise suspicion. A progressive small fiber sensorineuropathy with abnormalities of autonomic function is often seen with the hereditary TTR amyloidoses. In such cases, a peripheral nerve biopsy should always be examined pathologically with the diagnosis of amyloidosis in mind, as amyloid deposits are often not appreciated on routine histologic stains (Figure 79-4). The possible diagnosis of amyloidosis should be considered in any subject who presents with restrictive cardiomyopathy with or without orthostatic hypotension. Amyloid cardiomyopathy may give an anginal syndrome and often causes fatigue or dyspnea on exertion as signs of heart failure. Typical congestive features of heart failure, with peripheral edema, ascites and pleural effusion, may not be seen until late in the course of the disease. The most valuable tests for this condition are electrocardiography, which typically shows low voltage often with a pseudo-anteroseptal myocardial infarction pattern; and echocardiography or cardiac magnetic resonance imaging, which reveal a thickened interventricular septum and left ventricular posterior wall and enlarged left atrium, if the restrictive hemodynamics have been present for a long time. Chronic renal failure with or without heavy proteinuria should raise the suspicion of amyloidosis, as should unexplained impotence in males and chronic constipation alternating with diarrhea in either males or females. The presence of vitreous opacities affecting vision in any subject with heart failure or renal failure should raise the possibility of TTR amyloidosis (39). As with most genetically determined diseases, family history can be very important in making the diagnosis. However, family history may be misleading, as the diagnosis of amyloidosis has often been confused with other diseases in previous generations, and many forms

of the amyloidoses, despite being autosomal dominant, fail to show complete penetrance.

If a patient with amyloidosis has a family history of similar disease, or if there is a strong suspicion of hereditary amyloidosis, DNA analysis is usually the best way to confirm this suspicion (121). The diagnosis of amyloidosis has first to be made by tissue biopsy of an affected organ, and although immunohistochemistry may be helpful in identifying the type of amyloid involved, the results of immunostaining are not always reliable. Most new patients who present with hereditary amyloidosis are not aware of the gene or specific mutation that is the cause of their disease, even if they have a positive family history. In this case, it is important for the diagnostician to narrow the field of differential diagnoses by analyzing the symptom complex, the ethnic origin of the patient or his or her ancestors, the age of onset of the disease and the duration of disease before death. Table 79-1 lists the known disease-associated mutations in TTR and identifies where in the world significant kindreds have been identified. Unless a patient's syndrome matches to that of a previously identified kindred with a specific mutation and geographic localization, it is probably not cost-effective to pursue direct DNA analysis for specific mutations. There are over 100 mutations in TTR that cause systemic amyloidosis, and although there is a polymerase chain reaction (PCR)-based test using specific restriction enzymes, allele-specific PCR, or induced mutation restriction analysis for each, it is not feasible to perform all of these tests to find the causative mutation. Instead, since automated DNA sequencing of TTR exons is now commercially available, this form of DNA diagnosis has become the most efficient means to detect amyloid-associated mutations. Single-strand conformation polymorphism remains a useful screening procedure for new TTR mutations and for testing large numbers of subjects for a specific mutation (65). At the protein level, TTR variants can be detected by isoelectric focusing, but this technique is difficult and not generally available (122). The same is true for immunoprecipitation of TTR and the identification of mutant forms by mass spectrometry (123). DNA testing for the other forms of hereditary amyloidosis, including apo A-I, lysozyme, fibrinogen A $\alpha$  chain and apo A-II, presents similar problems. None of these tests is readily available for the various mutations, and the clinician needs to consult one of the few laboratories dedicated to the study of amyloidosis. It is now relatively easy for the patient or physician to obtain the necessary information from the Internet (<http://www.mayoclinic.com/health/amyloidosis/DS00431>; <http://www.iupui.edu/~amyloid>; <http://www.bu.edu/amyloid/>; <http://www.amyloidosisupport.com/index.html>; <http://www.amyloidosisupport.com/>).

#### 79.2.4 Management

There are three aspects to management of the patient with hereditary amyloidosis. First, the availability of

DNA analysis allows the patient to have the benefit of a definitive diagnosis and avoid extensive, costly and time-consuming medical evaluations searching for other diagnoses. Unfortunately, many patients with hereditary amyloidosis have already undergone cardiac catheterization, coronary angiography, multiple organ biopsy and even psychiatric evaluation before the diagnosis of amyloidosis has been entertained. Once a mutated allele associated with a specific form of amyloidosis has been identified, DNA testing becomes available for at-risk individuals in the family, and these individuals may benefit from the results of this testing. Testing, of course, needs to be accompanied by proper counseling as to the genetics of the specific disease and the prognosis based on current knowledge. The identification of specific mutations associated with amyloidosis has made prenatal testing available; however, to date only prenatal testing for TTR mutations has been reported (124,125). Either amniotic fluid or chorionic villus sampling is adequate for this first-trimester test, and results can be obtained within 48h if the specific mutation in the parent is known.

A second aspect of the management of amyloidosis is the nonspecific therapies that might improve quality and length of life. For instance, a number of commonly used drugs aggravate the heart failure associated with restrictive cardiomyopathy. Treatment for chronic diarrhea, gastroparesis, urinary retention and dysesthesias may help quality of life. Cardiac pacing and renal dialysis both may prolong life.

The third aspect of patient management is centers on specific therapy or the lack thereof. In the last 20 years, approximately 2000 liver transplantations have been carried out as a specific treatment for TTR amyloidosis (126,127); (<http://www.fapwtr.org/ram1.htm>). Liver transplantation results in rapid loss of variant TTR from the plasma, as TTR is synthesized predominantly in the liver. The greatest success has been in patients with the Val30Met TTR mutation. The most immediate effect has been improvement of gastrointestinal function and possibly hypotension. There has been a report of improvement in nerve myelination in patients who have had liver transplantation early in the course of their disease (128,129). Unfortunately, there is now definite evidence that progression of systemic amyloidosis occurs in some patients who have had liver transplantation. This has been found to be true in patients with the Glu42Gly, Thr60Ala, Ile84Asn and Cys10Arg mutations. Biochemical analysis of amyloid deposits in tissues of patients who died 3–5 years after liver transplantation have shown that normal TTR can continue to form amyloid after variant TTR has initiated the process but is no longer present (130,131). Renal transplantation in patients with fibrinogen A $\alpha$  chain amyloidosis usually results in amyloid deposition in the transplanted organ within 1–10 years. However, combined kidney and liver transplantation has shown good results, and it has been suggested that since normal fibrinogen is not found in the amyloid fibrils,

liver transplantation may be a cure for the disease. One patient is still alive after more than 12 years without disease progression and recently liver transplantation done prior to end-stage renal disease requiring concurrent kidney transplantation has been done (132,133). A few liver transplantations have been done in patients with apo A-I amyloidosis, and may delay progression of disease (134). Apo A-I is synthesized in the liver and in the gastrointestinal tract, and it is not known whether both the organs or just the liver is the source of the plasma precursor of the amyloid fibril deposits. A number of cardiac transplants have been done for patients with apo A-I cardiomyopathy and appear justified since this form of amyloidosis is very slowly progressive. Renal transplantations have also been done for patients with apo A-II amyloidosis since the renal disease is also slowly progressive (135).

To date, research on gene therapy for the hereditary amyloidoses has not been fruitful. With these diseases, the challenge is to find a means to stop the production of a protein that is not wanted, instead of producing an enzyme or other protein that is necessary for normal life, as is the object in most of the autosomal recessive diseases. For TTR amyloidosis small organic molecules that thermodynamically stabilize the TTR tetramer are being tested for treatment of the amyloidosis. Also, antisense oligonucleotides specific for TTR have been shown to decrease hepatic production of TTR in mice transgenic for Ile84Ser TTR and promise a possible specific therapy for this amyloidosis (136).

## 79.3 HEREDITARY LOCALIZED AMYLOIDOSIS

There are a number of localized forms of hereditary amyloidosis, each characterized by a specific protein that, because of a mutation in structure or a genetically determined alteration in metabolism, gains the features to participate in amyloid fibril formation. In most cases, the localized nature of the amyloid deposition is the result of synthesis of the fibril precursor protein that is restricted to the specific organ or tissue involved. There are, however, other factors necessary for the generation of amyloid deposits, and these must be present in proximity to the site of synthesis of the amyloid precursor protein. In most forms of localized amyloidosis, the fibril subunit protein is a proteolytic fragment of a larger precursor protein. Therefore, proteases that generate these fragments must be present and functional in the tissue where amyloid fibril deposition occurs. The same must be true for the various forms of proteoglycans, which are invariably part of amyloid deposits. As with the systemic forms of amyloidosis, once the amyloid fibrils are formed they must be resistant to removal by any localized tissue mechanisms.

### 79.3.1 Alzheimer Disease

By far, the most common form of localized amyloidosis is seen in Alzheimer disease. Amyloid deposits,

which are localized to cerebral cortical tissues and blood vessels, contain a 39- to 42-amino acid residue internal fragment from the C-terminal portion of a precursor protein expressed in the CNS (137). This protein,  $\beta$ -amyloid precursor protein ( $\beta$ -APP), is coded by a single gene on chromosome 21 and has several alternatively spliced transcripts, the largest encoding a protein of 770 amino acid residues (138). A few forms of familial Alzheimer disease are the result of point mutations in the  $\beta$ -APP gene that causes early-onset autosomal dominant dementia (139–142). A larger number of familial forms of Alzheimer disease are the result of mutations in the presenilin genes (PS1 and PS2) localized to chromosomes 14 and 1, respectively (143–145). The majority of cases of Alzheimer disease, however, is age related and does not show simple mendelian genetics. A current hypothesis for pathogenesis is that mutations associated with hereditary forms of Alzheimer disease accelerate the age of onset and progression of amyloid plaque formation, which is a normal aging phenomenon and may be modulated by such factors as apolipoprotein E.

### 79.3.2 Gerstmann–Sträussler–Scheinker Disease

Gerstmann–Sträussler–Scheinker disease (GSS) is another hereditary form of amyloidosis localized to the CNS (146). In this neurodegenerative disease, the amyloid deposits are derived from the prion protein, which is also associated with Creutzfeld–Jakob disease and other transmissible forms of spongiform encephalopathy (147,148). Variant forms of GSS are associated with missense mutations or numbers of octapeptide repeats in the prion gene localized to chromosome 20 (149). Pathogenesis is hypothesized to be related to transition in the tertiary structure of a protease-sensitive form of prion protein to a protease-resistant form that is capable of forming  $\beta$ -pleated sheet fibrils. Considerable variability in the clinical expression of the prion diseases is seen, and pathologic manifestations may include varying degrees of spongiform encephalopathy, cortical amyloid deposits and amyloid angiopathy. However, all are adult-onset diseases with autosomal dominant inheritance, manifested as progressive neurodegeneration.

### 79.3.3 British Dementia

Another form of localized amyloidosis limited to the CNS is the autosomal dominant familial British dementia, characterized by progressive dementia, spasticity and cerebellar ataxia (150). In this condition, cerebral amyloid angiopathy, non-neuritic and perivascular plaques, and neurofibrillary tangles represent the pathology. The disease is the result of a mutation in the stop codon for the *BRI* gene, which is localized to chromosome 13

(151). Owing to a single base substitution in the stop codon, a larger 277-residue protein is produced. A carboxyl-terminal fragment containing 34 amino acid residues of the mutated protein is the ABRI (Amyloid BRI) subunit. A similar syndrome with dementia in a Danish kindred is associated with a 10-nucleotide duplication proximal to the stop codon of the *BRI* gene. This results in a new C-terminal peptide that is the precursor of amyloid fibrils (152).

### 79.3.4 Corneal Dystrophies

A number of corneal dystrophies are examples of localized amyloidosis that are genetically determined (153) (Figure 79-5). Because of the localized nature and small amount of amyloid in the corneal tissues, the chemical nature of the amyloid deposits remained unknown until recently, when genetic studies and molecular biology techniques identified causative genes and mutations. Lattice corneal dystrophy (type 2), which is related to mutations in the gelsolin gene, was the first corneal amyloid to be chemically characterized, but this is a systemic disease and the protein structure was determined from fibrils isolated from major organs (97). A number of point mutations in the Big-h3 gene, localized to chromosome 5q31, have been found to cause varying phenotypes of corneal dystrophy (154,155). Mutations in the M1S1 gene (chromosome 1p), which encodes a gastrointestinal tumor-associated antigen, have also been found to cause corneal amyloid deposition (156). Although it is now possible to separate several of the various types of corneal dystrophy by DNA analysis, chemical characterization of the deposited amyloid fibril proteins has been delayed by the small amount and localized nature of the deposits. Given the unique environment of the cornea, characterization of the proteolytic processing and factors involved in deposition of amyloid fibrils in these diseases may be very revealing for amyloid fibrillogenesis in general.

**FIGURE 79-5** Amyloid deposits (arrow) in familial corneal dystrophy.

### 79.3.5 Other Localized Amyloidoses

There are numerous other forms of localized amyloidosis that are expressed in a familial manner. In two of these, the amyloid subunit protein has been identified. Isolated atrial amyloid contains a 28-amino acid residue carboxyl-terminal peptide of atrial natriuretic peptide (157,158). In most cases, deposition of this form of amyloid in the cardiac atria is age related and associated with chronic congestive heart failure. The familial atrial standstill syndrome is associated with this type of amyloid deposition and is inherited as an autosomal dominant condition (159). Amyloid that is deposited in medullary carcinoma of the thyroid is derived from procalcitonin (160). In the familial form of medullary carcinoma of the thyroid, an autosomal dominant condition that may be associated with other endocrinopathies, the amyloid deposition may be a result of overproduction of the amyloid precursor procalcitonin, as no structural defect or mutation in the amyloid precursor protein has been identified (161).

## 79.4 HEREDITARY NON-AMYLOID PROTEIN DEPOSITION DISEASE

While the number of amyloid proteins continues to grow, attention is now being directed toward diseases in which protein deposits occur intracellularly and the protein may or may not form fibrillar structures. Some of these diseases are hereditary and, as with most inherited forms of amyloidosis, are autosomal dominant. Included in this group are Huntington disease, frontotemporal dementia linked to chromosome 17, and familial Parkinson disease.

In Huntington disease, the disorder is associated with expanded CAG repeats in the Huntington gene (chromosome 4). Intranuclear deposits of the expressed protein with polyglutamine sequences are found in affected individuals, but the role of these protein deposits in the pathogenesis of the neurodegeneration is not known. Pick disease is characterized by presenile dementia with circumscribed cerebral atrophy. In this disease, protein deposits (Pick bodies) within the cytoplasm of cortical neurons contain abnormal forms of the microtubule-associated protein tau (162). Familial forms of Pick disease are associated with mutations in the tau gene (chromosome 17) and appear to change the ratio of expressed isoforms of tau protein (145). The role of protein deposition in the pathogenesis of the disease is still not known. Autosomal dominant Parkinson disease is associated with intracellular deposits that contain  $\alpha$ -synuclein. In a few families with hereditary Parkinson disease, mutations in the  $\alpha$ -synuclein gene (chromosome 4) have been found to be the cause of the disease (163).

Recently, families with progressive myoclonus epilepsy and dementia have been found to have intraneuronal

**FIGURE 79-6** Intraneuronal nonamyloid deposits contain mutant neuroserpin in a patient with hereditary myoclonus epilepsy and dementia.

cytoplasmic inclusions of neuroserpin, a serine protease inhibitor (Figure 79-6). Two mutations in the neuroserpin gene (chromosome 3q26) have been found to cause these syndromes (164,165). Mutation in the ferritin light polypeptide gene also causes intracellular protein deposits associated with dementia. Both of these syndromes are examples of pathology associated with protein deposition without actual amyloid  $\beta$ -fibril formation. Although the significance of such protein deposits in the pathogenesis of dementia is not known, identification of variant forms of intracellular proteins in these neurodegenerative diseases will certainly add to our knowledge of neuronal function (166).

## 79.5 CONCLUSION

In conclusion, it is best to view the hereditary amyloidoses as diseases associated with the deposition of specific proteins, which may be structurally normal or abnormal depending on the etiologic factor in each case. In addition, protein deposition diseases may occur without amyloid fibril formation, but with similar clinical results. Study of these hereditary diseases can tell us much about normal cell formation and physiology, and may lead to therapies for many pathologic conditions.

### Biography

**Professor M D Benson** received a BA (1961), MS-Pathology (1964) and MD (1965) from the University of Vermont. He received professional training at Bellevue Hospital (Columbia University College of Physicians and Surgeons) and Boston University.

He joined the faculty of Indiana University in 1976 as Associate Professor of Medicine and became Professor of Medicine in 1981 and Professor of Medical Genetics in 1984.

Professor Benson is an internationally recognized expert in the field of amyloidosis. He has discovered the origin of several forms of hereditary amyloidosis, including those related to mutations in apolipoprotein-A1 and fibrinogen Aa-chain. His research has revealed structural changes of proteins, which are related to the transition of proteins the  $\beta$ -structure that is characteristic of amyloid fibrils. These studies have included basic research on proteins implicated in amyloidosis of human immunoglobulin (AL), reactive (SAA) and hereditary (TTR) forms of amyloidosis. His research has also lead to significant discoveries in the area of Alzheimer disease, a form of amyloidosis localized to the central nervous system.

Professor Benson was Chairman of the department of Medical and Molecular Genetics from 1996 to 1999. He is a member of the American Association of Immunologists, American Society of Clinical Investigation, Association of American Professors, American Society of Human Genetics, American Rheumatism Association, the Central Society for Clinical Research and the International Amyloid Society.

In 2003, *The Pasteur-Weizmann Board and the Servier Institute* presented in Paris, their prestigious inaugural award, “Pasteur-Weizmann/Servier International Prize in Biomedical Research” to *Dr Benson and his group*. This award recognized his pioneering research on “Amyloid” protein deposits. ([article link in French](#))

Dr. Benson and colleagues had also discovered a mutation in the Alzheimer amyloid protein, leading to the development of a widely used mouse model of Alzheimer disease.

**Interests**—Amyloidosis, with particular emphasis on the systemic forms including Immunoglobulin (Primary), Reactive (Secondary) and Hereditary Amyloidosis. Present interests include clinical studies of patients with all forms of amyloidosis, in addition to basic studies in pathology, biochemistry, genetics and molecular biology. Current research projects include studies on regulation of gene expression, synthesis and metabolism of plasma proteins, and tertiary structure of proteins. Studies of Alzheimer disease include DNA testing and structural characterization of amyloid plaque proteins. These studies have led to interest in other late-onset neurodegenerative diseases. Transgenic animal models are being used to study pathogenesis of human disease. This is a new area which undoubtedly will lead to new direction in research.

## Immunodeficiency Disorders

*Rochelle Hirschhorn, Kurt Hirschhorn and Luigi D Notarangelo*

This article is a revision of the previous edition article by Rochelle Hirschhorn and Kurt Hirschhorn, volume 2, pp 1835–1857, © 2007, Elsevier Ltd.

### 80.1 INTRODUCTION

The immunodeficiency diseases are part of a spectrum of conditions involving defects in host defense against infections. Adequate host defense is dependent on the interaction between phagocytic cells, immunocompetent cells and their products, and the complement system. Diseases involving disorders of phagocytes and deficiencies of complement components (innate immunity) are discussed in subsequent chapters. Here, we will review disorders that affect the development and/or function of T and B lymphocytes and of natural killer (NK) cells, which play a central role in our ability to resist infection. It is the occurrence of infections with unusual frequency that draws our attention to the possibility that a patient may be suffering from a primary immunodeficiency disorder.

T and B lymphocytes are key components of the adaptive immune system. Adaptive immune responses are characterized by specificity and memory. The specificity is conferred by the expression of receptors (T cell receptor, B cell receptor) that recognize antigens. Furthermore, upon encounter with a foreign antigen, T and B lymphocytes produce memory cells that are capable of mediating prompt and more powerful responses upon subsequent challenge with the same antigen. On one hand, immune responses mediated by B lymphocytes include production of specific antibodies. On the other hand, cytotoxic T cells contribute to killing of virus-infected cells, whereas helper T lymphocytes produce cytokines that promote antibody production and inflammatory responses.

NK lymphocytes lack antigen-specific receptors and hence are not a component of the adaptive immune system; however, they play an important role in antiviral and anti-tumor immune responses. Several forms of immune deficiency due to impaired development and/or function of T lymphocytes are also characterized by defects of NK cells; therefore, these conditions are discussed in this chapter. Another important function of the adaptive immune system is the ability to distinguish self- versus non-self antigens, so that exposure to foreign antigens results in a protective immune response, whereas self-antigens are tolerized. In a number of immune deficiency diseases, this self/non-self discrimination is

compromised, leading to autoimmunity. Therefore, the discovery of autoimmune phenomena along with infection represents another clue that may help suspect an immune deficiency disease.

Primary immunodeficiencies are classified according to the underlying defect (1). In particular, in this chapter we will review:

- (1) Combined Immunodeficiencies: These are disorders with abnormal development and/or function of T lymphocytes. In most of these cases, antibody responses are also compromised, either because of an associated developmental defect of B lymphocytes, or because of the impaired function of helper T lymphocytes;
- (2) Antibody deficiencies: These disorders include defects that affect development and/or function of B lymphocytes, without affecting T lymphocytes;
- (3) Disorders of immune dysregulation, in which there is an impairment of immunological tolerance or an inability to extinguish immune responses in the face of defective cytolytic function;
- (4) Immunodeficiency syndromes: These include a heterogeneous group of disorders, in which immune deficiency is an important component, but other extra-immune manifestations also exist.

### 80.2 SPECIFIC INHERITED IMMUNODEFICIENCY DISORDERS

#### 80.2.1 Combined Cellular and Humoral Immune Defects

**80.2.1.1 Severe Combined Immunodeficiency Disease.** Severe combined immunodeficiency disease (SCID) is characterized by profound defects of both cellular and humoral immunity and includes a heterogeneous group of genetically determined disorders that affect T cell development (1,2). In some cases, development and/or function of B lymphocytes and/or NK cells are also compromised (Figure 80-1); the presence or absence of these lymphocyte subsets represents the basis of immunological classification of SCID.

**FIGURE 80-1** Schematic representation of genetic defects (in red and italic) that have been identified in patients with Severe Combined Immune Deficiency. ADA: adenosine deaminase; AK2: adenylate kinase 2; CD3D: CD3 delta; CD3E: CD3 epsilon; CD3Z: CD3 zeta; DCLRE1C: Artemis; IL2RG: Interleukin-2 receptor gamma chain; IL7R: Interleukin-7 receptor alpha; JAK3: Janus-associated kinase 3; LIG4: DNA ligase 4; NHEJ1: Cernunnos; PNP: purine nucleoside phosphorylase; PRKDC: DNA-PK catalytic subunit; TRAC: T cell receptor alpha constant. B: B lymphocyte; Bp: B cell progenitor; CLP: common lymphoid progenitor; DN: CD4<sup>+</sup> CD8<sup>-</sup> double negative thymocyte; DP: CD4<sup>+</sup> CD8<sup>+</sup> double positive thymocyte; HSC: hematopoietic stem cell; NK: Natural Killer lymphocyte; NKp: Natural Killer cell precursor; T/NKp: common progenitor to T and NK lymphocytes.

SCID has a prevalence of 1:50,000–1:100,000 live births and is the most rapidly progressive and devastating of the primary immunodeficiency syndromes. SCID may be inherited as an autosomal or X-linked recessive. This syndrome was originally called “essential lymphocytophthisis,” “thymic alymphoplasia,” or “Swiss-type agammaglobulinemia.” Patients with this syndrome within the first few months of life present with severe, persistent or recurrent infections due to bacterial, viral, and fungal pathogens. Opportunistic infections (*Pneumocystis jiroveci* pneumonia, *Cytomegalovirus* infection) are common and are a frequent cause of interstitial pneumonia and chronic diarrhea, leading to failure to thrive (3–5). Candida infection is almost universal. A morbilliform exanthematous rash or exfoliative dermatitis may develop. This may reflect graft-versus-host disease (GvHD) due to transplacental passage of maternally-derived T lymphocytes or use of unirradiated blood products. In patients carrying hypomorphic mutations in SCID-causing genes, development of a skin rash may also reflect the presence of autologous and oligoclonal T cells that infiltrate and attack the skin. This condition is also known as Omenn syndrome, and is characterized by erythroderma, lymphadenopathy, liver and spleen enlargement, severe infections, eosinophilia, and increased serum IgE.

Other manifestations of GvHD in patients with SCID and maternal T cell engraftment are represented by hepatosplenomegaly, diarrhea and eosinophilia. On the other hand, it should be noted that maternal T cells are detected in as many as 50% of all cases of SCID (6), and

yet only a fraction of them show clinical manifestations of GvHD (7). Immunization with live vaccines (e.g. rotavirus, oral poliovirus vaccine, Bacillus Calmette–Guerin (BCG)) can have disastrous consequences in infants with SCID and should not be performed. The course of SCID, even without iatrogenic complications, is rapidly progressive, associated with wasting and runting, and, if untreated, fatal by 2 years of age.

Virtually all parameters of cellular and humoral immunity are abnormal. Patients usually have absent tonsils, small or absent lymph nodes, and absent thymic shadow. Lymphopenia is detected in approximately 70% of the patients. Enumeration of lymphocyte subsets may provide useful information on the underlying genetic defect (5). In vitro proliferative responses to mitogens are absent or markedly reduced. Immunoglobulins are usually absent, although passively transferred maternal immunoglobulin (Ig) of the IgG class can be present as long as the first 6 months of life. Failure of development of serum IgA and/or IgM (which do not cross the placenta) can often provide a sensitive marker for immunoglobulin abnormality early in life. Even in patients with a normal number of B lymphocytes, there is inability to mount specific antibody responses. Pathologically, there is a lack of normal lymph node architecture and a small, dysplastic or fetal thymus.

Recently, a newborn screening test for SCID has become available. The test is based on polymerase chain reaction (PCR)-mediated amplification of T cell receptor excision circles (TRECs) from a dried blood spot collected at birth (8,9). TRECs are a by-product of T cell receptor

(TCR) gene rearrangement and persist in newly developed T lymphocytes that express the  $\alpha\beta$  form of the TCR (10), but are diluted off with subsequent proliferation of cells in the periphery. Therefore, enumeration of TREC levels provides important information on thymic function.

Recently, it has become clear that, as in most other inborn errors, there is significant clinical variation in phenotypic manifestations, including age at diagnosis, which may range from the classically described infantile onset to as late as early-adult onset (11). This variation is most likely due to different mutations in the responsible genes, leading to greater or lesser expression of the gene product. Autoimmunity and increased risk of malignancies are frequently observed in patients with delayed-onset of the disease.

Treatment of SCID is based on hematopoietic stem cell transplantation (HSCT). Optimal results (>90% survival) are obtained if the transplant is performed from an HLA-matched sibling (12,13). Alternatively, HSCT can be performed from a matched unrelated donor or from a haploidentical parent; in the latter case, mature T lymphocytes must be removed from the graft to avoid GvHD. Excellent results (>95% survival) have been reported if HSCT for SCID is performed at <3.5 months of life (13), emphasizing the significance of newborn screening for SCID. Regular administration of Igs, use of prophylactic antibiotics and contact precautions should be used while waiting for HSCT. Infections should be sought and treated aggressively. When indicated, transfusion of blood products should be irradiated to prevent transfusional GvHD, and should be from CMV-negative donors to avoid the risk of viral transmission.

Alternative forms of treatment include enzyme replacement therapy and gene therapy, which have been successfully used in some forms of SCID, as described below.

**80.2.1.2 Pathophysiology of SCID.** SCID includes a heterogeneous group of genetically determined conditions that result in severe and early blocks in the development of T lymphocytes; some of these forms also affect differentiation of B and NK lymphocytes. These blocks correspond to critical steps in T cell development that mark fundamental mechanisms in T cell biology.

Hematopoietic stem cells (HSCs) give rise to common lymphoid progenitors (CLPs), from which all major lymphocyte subsets (T, B, NK cells) derive. Upon seeding to the thymus, CLP receive instructive signals through Notch that promote commitment to the T cell lineage. These signals require the presence of thymic stromal cells. Furthermore, early thymic progenitors undergo significant expansion in response to cytokines, in particular interleukin-7 (IL-7).

Genetic defects that compromise survival of lymphoid progenitors or their ability to respond to IL-7 are responsible for some forms of SCID. Rearrangement of the TCR loci is a key step in T cell development, and is accomplished through the process of V(D)J recombination, whereby Variable (V), Diversity (D) and Joining (J) elements of the TCR are brought together. V(D)J recombination is initiated

by the recombinase activating gene (RAG) proteins RAG1 and RAG2, that recognize recombination signal sequences (RSS) that flank V, D, and J elements. The RAG proteins introduce double strand breaks in the DNA; this is followed by formation of a complex that brings together V, D and J elements. Next, proteins of the non-homologous end joining (NHEJ) pathway mediate repair of the double strand DNA breaks, resulting in sealing of the coding ends, and deletion of the intervening DNA sequence that is circularized as TREC. As a result of this process, expression of a pre-TCR (composed of TCR $\beta$  chain and a pre-T $\alpha$  chain) is allowed on the cell surface, in combination with CD3 chains, thereby permitting delivery of signals that promote progression to later stages in T cell development. Defects of the RAG genes, of genes involved in NHEJ and of CD3 chains all result in SCID by arresting T cell development at an early stage. In contrast, genetic defects that affect late steps of T cell development and/or that interfere with the function of T cells without preventing generation of mature T lymphocytes do not cause SCID, but rather are classified as “combined immunodeficiencies.”

## 80.2.2 X-linked SCID

The most common form of SCID affects males and is inherited as an X-linked recessive disorder. Typically, these patients have low numbers of T and NK cells, and a normal number of B lymphocytes (T<sup>-</sup> B<sup>+</sup> NK<sup>-</sup> SCID). In spite of the presence of B lymphocytes, they have low immunoglobulins and fail to produce specific antibodies. Female carriers are clinically unaffected, but show skewed X-chromosome inactivation in T cells and NK lymphocytes (14). Furthermore, unswitched (IgM<sup>+</sup>) B lymphocytes from female carriers display a random pattern of X-chromosome inactivation, whereas switched (IgM<sup>-</sup>) B cells display skewed X-inactivation (15). Altogether, these data strongly indicated that T and NK lymphocyte precursors that express the normal copy of the gene have a strong selective advantage and that a similar advantage is also observed in the B cell compartment at later stages of maturation.

The gene responsible for X-linked SCID was mapped to Xq13 in 1987 (16). In 1992, the *IL2RG* gene, encoding for the  $\gamma$  chain of the interleukin-2 receptor (IL-2R $\gamma$ ) was cloned (17); one year later it was mapped to Xq13 and mutations of this gene were identified in patients with X-linked SCID (18,19). IL-2 is a potent stimulator of immune responses, and it binds to a heterotrimeric receptor composed of  $\alpha$ ,  $\beta$ , and  $\gamma$  chains. Although it was originally thought that X-linked SCID was caused by mutations of IL-2R $\gamma$  that prevented IL-2 signaling, it was soon discovered that the IL-2R  $\gamma$  chain is also a component of other interleukin receptors, including IL-4R, IL-7R, IL-9R, IL-15R and IL-21R (18,20–24). For this reason, the IL-2R $\gamma$  chain was renamed as common  $\gamma$  chain, or  $\gamma_c$ . Studies in mice have shown that IL-7 plays a critical role in T cell development (25,26), whereas IL-15 is essential to promote differentiation of NK lymphocytes

(27,28). Thus, the T<sup>-</sup> B<sup>+</sup> NK<sup>-</sup> phenotype of patients with X-linked SCID results primarily by the lack of signaling through IL-7R and IL-15R.

A variety of mutations in the *IL2RG* gene have been identified in patients with X-linked SCID (29). Phenotypic variability has been reported, including milder cases (30), normal thymic morphology (31), residual development of T and/or NK lymphocytes (29,31–33), total absence of B cells (34), and presentation resembling hemophagocytic lymphohistiocytosis (35). The development of autologous T lymphocytes has also been observed in a patient with X-SCID after spontaneous somatic gene reversion. The reversion event occurred in a lymphoid progenitor, rather than a stem cell, and the patient, therefore, displayed a partial reconstitution of the T-cell compartment that lasted for only a few years (36).

Approximately one third of the cases of X-linked SCID represent new mutations; this is consistent with what observed in other X-linked disorders. Identification of the disease-causing mutation in a patient allows prenatal diagnosis and carrier detection (37). In some cases, maternal germ line mosaicism has been demonstrated, emphasizing the need to search for mutations in the offspring, even when the mother of an affected child is not identified as a carrier (38). HSCT is the therapy of choice, as it is for all forms of SCID. Successful in utero HSCT has been reported in a few cases (39,40), however this treatment carries the avoidable risk of GvHD. Reconstitution of T cell immunity is typically achieved in infants with X-linked SCID and persists long-term, even after unconditioned T-cell depleted haploidentical HSCT (41). Reconstitution of B cell function is more problematic (42), unless donor B cell engraftment is achieved. This defect reflects failure of autologous, genetically-defective B lymphocytes, to respond to IL-21 and undergo plasma cell differentiation (43). Moreover, initial reconstitution of NK cell count after HSCT for X-linked SCID is often followed by progressive decline of these cells. Whether NK cell deficiency contributes to the higher risk of warts due to papillomavirus infection that has been reported after HSCT for X-linked SCID remains to be established (44). Gene therapy has been successfully used in infants with X-linked SCID (45–47); however, five of 20 infants with X-linked SCID treated by gene therapy have developed leukemic proliferation. This reflected insertional mutagenesis, with integration of the transgene near oncogenes (especially LMO-2), thereby inducing their transcriptional activation (48,49).

### 80.2.3 Autosomal Recessive SCID

**80.2.3.1 Adenosine Deaminase Deficiency.** In 1972, Giblett et al. (50) described two children who were presented with autosomal recessive combined immunodeficiency with both lacking the enzyme adenosine deaminase (ADA). This represented the first molecular defect defined in immunodeficiency disorders (51).

ADA deficiency is the second most common form of SCID, accounting for 20–30% of autosomal recessive SCID or 10–20% of all SCID (52). Most patients present with a syndrome indistinguishable from classic SCID. They are considered to have absence of both T and B cells but may initially retain B cells. The most severely affected ADA SCID cases can present with prominence of the costochondral junctions on physical examination, and cupping and flaring on radiography. The spectrum of ADA deficiency is also known to encompass a later onset, milder immunodeficiency disorder with persistence of some function and longer life span, to a syndrome of late-adult-onset disease. These later onset cases often initially present with recurrent sinopulmonary infections and may develop autoimmune phenomena, hyper-IgE, and asthma. However, in retrospect, lymphopenia was present from infancy. The rare adult-onset cases have been marked by warts and herpetic manifestations.

A variety of mutations have been identified in patients with ADA deficiency (51,53–56), and there is relatively good correlation between mutation, biochemical phenotype in vitro, biochemical phenotype in vivo (metabolites and enzyme activity), and clinical picture (57,58). In particular, hypomorphic mutations (including some splice site mutations) are often responsible of milder and delayed presentations. A number of children have also been found who lack ADA in red blood cells, but show sufficient residual activity in their lymphocytes to sustain normal immune function (55,59,60). Somatic mosaicism has been reported as a modulator of phenotype, resulting in milder disease (61–63). These observations indicate that the normal cells have a selective advantage, an important point with respect to prognosis for gene therapy.

Prenatal diagnosis by amniocentesis or chorionic villus sampling, as well as carrier detection, can be achieved by enzymatic or, when the mutation is known, by molecular methods (64).

Children with ADA deficiency show accumulation of adenosine and deoxyadenosine (the substrates of the deficient enzyme) and of their phosphorylated derivatives, in various tissues. These compounds, and especially, deoxy-ATP (dATP) are toxic to highly proliferating cells, such as T lymphocytes, and cause apoptosis and tissue damage. Moreover, there is also secondary inhibition of SAH hydrolase in ADA deficiency. Accumulation of toxic metabolites may also cause myeloid dysplasia and bone marrow hypocellularity (65), pulmonary alveolar proteinosis (66), hepatic failure (67), osteoblast insufficiency (68), and neurological abnormalities such as developmental delay, sensorineural hearing defects, motor dysfunction and behavioral problems (3,69,70). Accumulation of deoxyadenosine has been reported to result in increased chromosome breaks (51), and this may explain the occurrence of a rare tumor, multicentric dermatofibroma protuberans, in several ADA-deficient patients (71). Finally, abnormalities of

purine metabolism interfere with the function of regulatory T (Treg) cells, thereby contributing to autoimmune manifestations (72).

The therapy of choice for this disorder is HSCT. Best results, with complete immunological reconstitution, resolution of the metabolic abnormalities and 88% survival rate, are obtained if an HLA-matched family donor is available. In contrast, HSCT from haploidentical parents or unrelated donors is associated with higher morbidity and mortality (12,73,74). Neurological abnormalities, including sensorineural hearing abnormalities, mental retardation, motor dysfunction and behavioral problems, may persist even after successful HSCT (75).

A modified preparation of calf intestinal ADA coupled to polyethylene glycol (PEG-ADA) has been injected into over 180 ADA-deficient patients worldwide, resulting in sufficiently high circulating enzyme levels to more completely reduce toxic metabolites, restore immunofunction in most of the patients, and result in a 20-year survival rate of 78% (73,76).

Clinical response to enzyme replacement therapy (ERT) has been generally good, as measured by normal growth and development, ability to attend school, absence of opportunistic infections, and normal recovery from varicella and other viral diseases. Immune reconstitution, as measured by lymphocyte counts and in vitro function, has been less complete, and approximately 20% of patients, predominantly with infantile-onset disease, show slower and lesser improvement.

Half of the patients treated by ERT continue to require immunoglobulin replacement therapy (73). Moreover, gradual decline in lymphocyte counts, abnormalities of lymphocyte function and impaired production of T and B lymphocytes have been documented (77–79).

Virtually all patients on PEG-ADA develop antibody against the bovine ADA protein that in approximately 10% of cases is neutralizing, requiring increase of the dosage or discontinuation of ERT in an attempt to achieve desensitization (80,81). In some cases development of neutralizing antibodies was associated with irreversible loss of efficacy, severe autoimmune complications and death (73). Furthermore, deaths due to liver cancer, late infections and chronic lung disease have been documented in patients receiving ERT (73), and the very-long-term effect of this therapy remains to be determined (53).

The most recent approach to therapy is gene therapy. The early trials were based on introduction of the ADA complementary DNA into patient's T cells by means of a retroviral vector (82,83). Subsequent attempts targeted patient's cord blood stem cells (84), but use of ERT in these patients prevented clear assessment of efficacy of gene therapy. Following the demonstration that transduced T lymphocytes may have a selective advantage, multilineage engraftment of gene-corrected cells, metabolic correction, and improvement of immune function have been achieved in ADA-deficient patients who were

not treated with PEG-ADA and received genetically modified CD34<sup>+</sup> cells after preparative nonmyeloablative chemotherapy (85,86). In a series of 15 patients treated in Milan (Italy), all of which are currently alive, progressive immune reconstitution has been observed, with restoration of T cell immunity with no need for ERT in 13 of them. One patient continued to experience severe autoimmunity and required immune suppression (87). Encouraging results have been also obtained in smaller series in London and in the United States (74,88). Immune reconstitution after gene therapy for ADA deficiency is associated with shortening of telomeres in T lymphocytes, but not in bone marrow cells, indicating that homeostatic proliferation of T cells contributes to immune reconstitution and is not associated with stem cell senescence after gene therapy (88a). Contrary to the experience in X-linked SCID (see above), none of the patients treated by gene therapy for ADA deficiency worldwide have developed leukemic proliferation as a result of insertional mutagenesis.

**80.2.3.2 FOXN1 Deficiency.** The *FOXN1* genes encodes for a transcription factor that is required for the development and maturation of the thymus stroma and eccrine glands (89). Biallelic *FOXN1* mutations cause an autosomal recessive SCID phenotype in which lack of circulating T lymphocytes is associated with alopecia (90). There is complete blockage of CD4<sup>+</sup> cell development; a low number of oligoclonal CD8<sup>+</sup> T cells may be detected (91). This disease is the human equivalent of the *nude* phenotype in mice. In one affected fetus, immune deficiency was also associated with anencephaly and spina bifida (92). Treatment is based on thymus transplantation (93). However, HSCT from an HLA-identical sibling may also be used; in this case, reconstitution of CD4<sup>+</sup> cells is accomplished through homeostatic proliferation of T lymphocytes contained in the graft (94).

**80.2.3.3 Reticular Dysgenesis.** Reticular dysgenesis is a form of autosomal recessive SCID characterized by the association of severe lymphopenia, agranulocytosis and sensorineural deafness (95,96). The disease is due to defects in adenylate kinase 2 (AK2) that regulates the levels of ADP and AMP in mitochondria. Another isoform of adenylate kinase (AK1) is expressed in most tissues, but not in T lymphocytes and neutrophils. Consequently, AK2 deficiency causes disruption of mitochondrial membrane potential and apoptosis in these cells, resulting in SCID and agranulocytosis (97,98). AK2 is also expressed in the stria vascularis in the inner ear (98), and this may account for sensorineural deafness in patients with reticular dysgenesis. Patients with reticular dysgenesis are also prone to myelodysplasia (99). Treatment is based on HSCT, but results are less satisfactory than in other forms of SCID, and use of intensive conditioning is typically required to achieve engraftment (100).

**80.2.3.4 IL-7 Receptor Deficiency.** IL-7 serves an essential role in the proliferation and differentiation of early T cell progenitors. The IL-7R is a heterodimer

composed of the IL-7 $\alpha$  chain and the  $\gamma$ c. Mutations of the *IL7R* gene (encoding for IL-7 $\alpha$ ) result in SCID with absence of T cells, and normal development of B and NK lymphocytes (T<sup>-</sup> B<sup>+</sup> NK<sup>+</sup> SCID) (101,102). A variety of mutations have been reported in the *IL7R* gene (103). However, development of oligoclonal, activated, autologous T cells resulting in Omenn syndrome has been also reported (104). HSCT allows full immune reconstitution, even if donor cell engraftment is restricted to T lymphocytes, with persistence of autologous B and NK cells.

**80.2.3.5 JAK3 Deficiency.** Cytokine receptors that contain the common gamma chain ( $\gamma$ c) recruit tyrosine kinases to deliver intracellular signaling. In particular, in all these receptors, the  $\gamma$ c is physically and functionally coupled to the Janus associated kinase 3 (JAK3) (105), whose gene has been mapped to chromosome 19p12. JAK3 deficiency is inherited as an autosomal recessive trait and results in an SCID phenotype that is indistinguishable from that of X-linked SCID, with absence of T and NK lymphocytes (106,107), reflecting lack of IL-7 and IL-15-mediated signaling, respectively. Identification of the mutation allows prenatal diagnosis (108). Phenotypic variability has been reported with development of autologous T cells (109), which in some cases partially retained JAK3 function, allowing survival into late adolescence or young adulthood (110). Successful immune reconstitution is typically achieved after HSCT (111), but warts may occur even long-term after transplantation (44). Furthermore, insufficient humoral immune reconstitution has been frequently observed in patients who attain donor T cell engraftment, but autologous B cell reconstitution, after unconditioned haploidentical HSCT (43).

**80.2.3.6 RAG-1 and RAG-2 Deficiency.** RAG deficiency represents an important cause of autosomal recessive SCID. Null mutations in the *RAG1* and *RAG2* genes impede V(D)J recombination, and hence result in complete lack of circulating T and B lymphocytes, with normal number of NK cells (112). Hypomorphic mutations in the same genes may also cause distinct phenotypes, including Omenn syndrome (113,114) and leaky SCID (with the presence of autologous T lymphocytes, but without the distinctive phenotypic features of Omenn syndrome). Even when present, autologous T lymphocytes are oligoclonal, and fail to respond normally to antigenic stimulation. More recently, it has been demonstrated that hypomorphic RAG mutations may cause a milder clinical phenotype, with delayed-onset infections, autoimmunity and granuloma formation (11). In one patient, RAG mutations were associated with idiopathic CD4 lymphopenia and preserved diversity of T cell repertoire (115). Treatment is based on HSCT, however, immunosuppression is typically needed pre-transplant in patients with Omenn syndrome to control the autoimmune and inflammatory manifestations of the disease. Furthermore, use of

chemotherapy is often required in Omenn syndrome to facilitate engraftment.

**80.2.3.7 Artemis Deficiency.** Artemis participates at NHEJ pathway of DNA double strand break repair, by opening the hairpins that seal the coding ends at V, D, and J elements that have been targeted by the RAG proteins. As the other components of the NHEJ pathway, Artemis plays a role in DNA repair that goes beyond V(D)J recombination. Accordingly, the clinical phenotype of Artemis deficiency is characterized by T<sup>-</sup> B<sup>-</sup> NK<sup>+</sup> SCID associated with several non-immunological problems, such as oral and genital ulcers, teeth abnormalities, dystrophic features of the gut mucosa (116,117). Increased cellular radiosensitivity in patients with Artemis deficiency reflects the important role of the protein in DNA repair (116). A partial form of the disease, with residual expression and function of the protein, is characterized by reduced number of circulating T and B lymphocytes, and unincreased risk of lymphoma (118).

The Artemis protein is encoded by the *DCLRE1C* gene, located on chromosome 10p (116,119). Artemis deficiency is inherited as an autosomal recessive trait and is particularly frequent among Navajo, Apache, and other Athabascan Indians (120). Treatment is based on HSCT, however, a high rate of complications (growth failure, diarrhea due to gut mucosa dystrophy) has been reported (121).

**80.2.3.8 Other Forms of T<sup>-</sup> B<sup>-</sup> NK<sup>+</sup> SCID Associated with Increased Cellular Radiosensitivity.** Autosomal recessive SCID associated with radiation sensitivity may also be due to defects of other genes involved in the NHEJ pathway. DNA ligase IV deficiency may present with a variable phenotype, characterized by microcephaly, increased sensitivity to radiations and radiomimetic agents, increased risk of bone marrow failure and of leukemia, and a variable degree of immunodeficiency (122). In some cases, the immunodeficiency may be so severe to cause a T<sup>-</sup> B<sup>-</sup> SCID phenotype (123–125).

Deficiency of Cernunnos (also known as XLF), another component of the NHEJ pathway, causes immunodeficiency with microcephaly and increased risk of bone marrow failure and myelodysplasia (126,127). The immunological phenotype is often characterized by the residual presence of T and B lymphocytes. Cernunnos is encoded by the *NHEJ1* gene.

One patient has been reported with autosomal recessive T<sup>-</sup> B<sup>-</sup> NK<sup>+</sup> SCID due to deficiency of the DNA protein kinase catalytic subunit (DNA-PKcs), encoded by the *PRKDC* gene (128).

All these forms of radiation-sensitive SCID can be successfully treated with HSCT; however, attention must be paid to reducing the risk of toxicity related to the use of chemotherapeutic agents during conditioning.

**80.2.3.9 Defects of CD3 Chains.** During T cell development, the pre-TCR and the TCR are expressed on the cell surface in association with the CD3 $\gamma$ ,  $\delta$ ,  $\epsilon$  and  $\zeta$  chains. Mutations of the *CD3G* gene (encoding for

the CD3 $\gamma$  chain) result in a variable degree of immunodeficiency with autoimmunity, but do not cause SCID (129). In contrast, null mutations in the *CD3D*, *CD3E* and *CD3Z* genes (that encode for CD3 $\delta$ , CD3 $\epsilon$  and CD3 $\zeta$  chains, respectively) impede signaling and cause autosomal recessive T<sup>-</sup> B<sup>+</sup> NK<sup>+</sup> SCID (130–134). Interestingly, somatic mutations of the *CD3Z* gene have been associated with partial postnatal development of T lymphocytes (133).

**80.2.3.10 T Cell Receptor Alpha Constant (TRAC) Chain Deficiency.** A homozygous nucleotide substitution affecting splicing of the TRAC transcript was identified in two affected individuals from apparently unrelated families with autosomal recessive immunodeficiency characterized by increased susceptibility to infections, autoimmunity (vitiligo, autoimmune hemolytic anemia) and allergy (eczema, eosinophilia) (135). The mutation was predicted to result in a TCR $\alpha$  chain protein lacking the transmembrane and cytoplasmic domains, which are essential for surface expression of the TCR $\alpha\beta$  complex. Consistent with this, circulating T lymphocytes expressed TCR $\gamma\delta$  or had an aberrant phenotype, with low expression of CD3 molecules and trace amounts of TCR $\alpha\beta$ . Proliferative responses to mitogens were variably reduced. In contrast, immunoglobulin levels were normal, and the patients were able to mount antibody responses to vaccine antigens. More recently, however, biallelic LCK mutation has been reported in a child with recurrent infections and autoimmunity. Expression of CD4 and CD8 protein on the surface of CD3<sup>+</sup> cells was markedly reduced, and *in vitro* T cell proliferation in response to CD3 stimulation was severely compromised (139a).

**80.2.3.11 CD45 Deficiency.** Deficiency of the CD45 protein tyrosine phosphatase causes impaired intracellular signaling in developing T lymphocytes. The disease is inherited as an autosomal recessive trait and is a rare cause of SCID (136,137). One patient was a compound heterozygote for a deletion and a point mutation at a splice site, while another was homozygous for a six-base pair deletion.

**80.2.3.12 p56/lck Deficiency.** One infantile-onset patient with SCID was found to have diminished expression of the protein tyrosine kinase p56/lck, possibly associated with a splicing abnormality in the gene (138). An adult with CD4 lymphopenia has been described with diminished expression of this protein, but no genetic abnormality has been found (139).

**80.2.3.13 Coronin-1A Deficiency.** Coronin-1A is a negative regulator of the Arp2/3 complex and of actin cytoskeleton reorganization. A biallelic dinucleotide deletion in the *CORO1A* gene has been identified in a patient with an atypical T<sup>-</sup> B<sup>+</sup> NK<sup>+</sup> SCID phenotype (140). *In vitro* proliferative responses to mitogens were reduced, but not absent, and the thymic shadow was visible at chest X-ray. The clinical history was characterized by recurrent infections, thrush, vaccine-induced varicella, and diarrhea due to rotavirus infection. In addition, there

was delay in language and motor development. The child survived with supportive medication until 4 years of age, when she received unrelated cord blood transplantation leading to immune reconstitution (141). The mechanism underlying the SCID phenotype is unclear. Several mouse models of Coronin-1A deficiency exist, which interfere with survival and/or egress of thymocytes.

## 80.2.4 Other Combined Immunodeficiency Diseases

Several genetic defects of T cell development are known, which allow for residual T cell development and function. The partial preservation of T lymphocyte development and function may account for delayed clinical onset and higher chance of survival beyond infancy even in the absence of HSCT. Nonetheless, clinical manifestations are often severe, and similar to those observed in patients with SCID, although autoimmunity is more frequent. HSCT is the treatment of choice, however, the presence of autologous T cells with residual function makes use of conditioning regimen necessary to achieve donor cell engraftment.

**80.2.4.1 Purine Nucleoside Phosphorylase Deficiency.** Genetic deficiency of purine nucleoside phosphorylase (PNP) results in a defect predominantly of cellular immunity and was the second specific genetic molecular defect described that results in immunodeficiency. PNP reversibly catalyzes the phosphorylation of the purine nucleosides guanosine, inosine, deoxyguanosine, and deoxyinosine and is thus the next enzyme in the purine salvage pathway following ADA. Therefore, PNP deficiency causes accumulation of all four nucleoside substrates (inosine, guanosine, deoxyinosine, and deoxyguanosine). Deoxyguanosine triphosphate (deoxy-GTP) is the major phosphorylated metabolite accumulated by PNP-deficient children, and like deoxy-ATP, is also an allosteric inhibitor of ribonucleotide reductase and could account for the specific effects of PNP deficiency on thymocyte development (142). Because the block is near the terminal portion of the major common pathway to uric acid, patients with complete PNP deficiency have low serum uric acid and excrete diminished amounts of uric acid.

PNP deficiency is rarer than ADA deficiency and is also inherited as an autosomal recessive trait. The PNP gene has been mapped to chromosome 14q13.1 (143). Missense mutations account for the majority of the mutations reported, however, nonsense mutations and splice site mutations have been also described (144).

The clinical onset of the disease may vary from 6 months to over 6 years of age, and is marked by severe infections, often sustained by opportunistic pathogens. Autoimmunity (especially autoimmune hemolytic anemia and other cytopenias) and progressive neurological abnormalities (including spastic tetraplegia, ataxia, and multifocal leukoencephalopathy) are very common (145).

Bone marrow dysplasia has been also observed (146). It is apparent that all the patients have eventually had severe T-cell dysfunction, as measured by marked reduction of T-cell numbers, reduced response to mitogens and allogeneic cells, and severe recurrent fungal and viral infections. In many children, preservation of humoral immunity has been demonstrated, as measured by normal numbers of B cells in the blood and of plasma cells in lymphoid tissue, normal to elevated immunoglobulin concentration in vivo, and normal antibody production.

HSCT is the therapy of choice, but persistence and progression of neurological defects may be observed even in patients who attain immune reconstitution.

**80.2.4.2 ZAP-70 Kinase Deficiency.** The Zeta Chain-Associated Protein of 70 kDa (ZAP-70) is a tyrosine kinase that phosphorylates the CD3 chains and participates at TCR-mediated signaling (147). Patients with Zap-70 deficiency have a virtual lack of CD8<sup>+</sup> lymphocytes; the number of CD4<sup>+</sup> cells is preserved, but they are unable to proliferate in response to mitogens and antigens (148–151).

They proliferate in response to stimulation with calcium ionophores and phorbol esters, which bypass the membrane-proximal steps in T cell activation. Inability of the T cells to respond to antigens in patients with ZAP-70 deficiency causes increased susceptibility to severe infections, resulting in a clinical phenotype that is indistinguishable from that of SCID. Heterogeneity of the clinical phenotype has been observed, with some patients showing delayed clinical onset and others presenting with features of atopic dermatitis, eosinophilia and increased serum IgE (152,153).

## 80.2.5 Major Histocompatibility Complex Class II Deficiency

The positive selection of CD4<sup>+</sup> thymocytes requires the interaction of thymocytes expressing a functional TCR with thymic epithelial cells (and dendritic cells) expressing self-antigens bound to HLA class II molecules, respectively.

Patients with MHC-II deficiency lack expression of HLA class II (D, DR, DQ, and DP) antigens. This group of patients is genetically heterogeneous, as evidenced by the existence of at least four complementation groups, two of which account for the majority of patients (154).

The genetic defects accounting for MHC-II deficiency do not involve the HLA II genes, but rather a set of genes that encode for transcriptional activators of HLA class II genes. In particular, MHC-II deficiency may be due to mutations of MHC class II transactivator *CIITA* (155), or of *RFX5* (156–158), *RFXAP* (159), and *RFXANK* (160) genes, which encode for the subunits of RFX that binds to the HLA promoter. The disease is more common in northern Africa; it is inherited as an autosomal recessive trait and is characterized by a marked reduction of the number of circulating CD4<sup>+</sup> cells. Patients

lack antigen-specific T-cell proliferative responses and show impaired specific antibody production; however, the T cells respond to polyclonal mitogens, such as PHA (161). There is increased risk of infections, including *P. jiroveci* pneumonia and severe bacterial and viral diseases. Patients are also unusually susceptible to *Cryptosporidium* disease, leading to protracted diarrhea and sclerosing cholangitis. Mutations in *CIITA* and in *RFXANK* have been described in cases of milder immunodeficiency (162,163). In most cases, patients die early in childhood, however, survival into adolescence and young adulthood has been also reported, especially if patients are maintained on immunoglobulin replacement therapy and antibiotic prophylaxis (164). Treatment with HSCT may be effective, but is often problematic, because it does not correct the defective expression of MHC-II antigens on thymic epithelial cells (164,165).

**80.2.5.1 Defective Expression of MHC Class I Antigens.** Lack of expression of MHC class I antigens impairs positive selection of CD8<sup>+</sup> T lymphocytes in the thymus. The disease is inherited as an autosomal recessive trait. It is genetically heterogeneous, and may be caused by mutations in the genes that encode for TAP1, TAP2 or Tapasin (166–168). TAP1 and TAP2 are subunits of a peptide transporter system that carries antigenic peptides to the lumen of the endoplasmic reticulum, where they associate with and stabilize class I MHC molecules complexed to  $\beta_2$ -microglobulin prior to transport to the lymphocyte surface. Tapasin links TAP to the HLA class I heavy chain.

The clinical phenotype of MHC class I deficiency is variable, but is often characterized by chronic inflammatory lung disease leading to bronchiectasis, nasal polyps, and vasculitic skin manifestations that may evolve into necrotizing granulomas, especially on the legs (169). The reasons underlying heterogeneity of the severity of the clinical phenotype are unclear, but are unlikely to depend on the type of the mutation, since variability of phenotype has also been reported in patients sharing the same mutation.

As a result of defective expression of HLA class I molecules, the number of CD8<sup>+</sup> lymphocytes is significantly reduced. However, some CD8<sup>+</sup> cells may develop; in particular, development of CD8<sup>+</sup> lymphocytes expressing the TCR $\gamma\delta$  form of the T cell receptor is not blocked. The cytolytic activity of NK cells is also maintained, and this may explain why patients with MHC class I deficiency are not uniquely susceptible to viral infections. On the other hand, the impaired expression of HLA class I antigens would not permit engagement of killer inhibitory receptors (KIRs) regulating the function of NK cells. Hence, NK cells from the patients could mount cytotoxic responses to autologous cells, contributing to the inflammatory and destructive lesions observed in the lungs and the skin. Increased surface expression of KIRs and of CEACAM1 in patients with TAP and Tapasin deficiency reduces this risk (170).

**80.2.5.2 CD8  $\alpha$  Chain Deficiency.** Homozygosity for a Gly111Ser missense mutation in the  $\alpha$  chain of CD8 was found to cause complete deficiency of CD8<sup>+</sup> lymphocytes (171). Variable severity of the clinical phenotype has been reported: one patient died of pulmonary complications after recurrent bacteria infections (171), whereas another patient has maintained good lung function, in spite of frequent infections (172).

**80.2.5.3 MST1/STK4 Deficiency.** The MST1 kinase (also known as STK4) is the human ortholog of the Hippo protein, a key component of a novel pathway that controls cell growth and apoptosis in *Drosophila*. Mutations of MST1 in humans cause an autosomal recessive form of combined immunodeficiency with marked and progressive loss of naïve T cells, recurrent bacterial and viral infections and autoimmune manifestations (173,174). A modest degree of intermittent neutropenia and heart defects have been also observed. Lymphocytes and neutrophils show increased loss of mitochondrial membrane potential, and MST1-deficient T cells show reduced expression of the transcription factor FOXO1, as well as of IL7R and BCL2. Altogether, these abnormalities cause reduced survival of naïve cells and neutrophils.

**80.2.5.4 DOCK8 Deficiency.** The dedicator of cytokinesis 8 (DOCK8) protein is a member of the DOCK family of intracellular signaling proteins that serve as guanine exchange factors for the Rho/Rac family GTPases. DOCK8 plays a critical role in cell adhesion, migration and signaling. Individuals with biallelic inactivating DOCK8 mutations present with signs of combined immunodeficiency: recurrent sinopulmonary infections, severe cutaneous viral infections due to HPV, HSV and VZV, and molluscum contagiosum. Furthermore, they show severe atopic dermatitis and are at increased risk for tumors. T and B cell lymphopenia, with marked reduction of naïve cells, defective in vitro lymphocyte proliferation (especially of CD8<sup>+</sup> cells), poor antibody production, low levels of IgM and markedly increased levels of IgE are immunological hallmarks of the disease (175,176). Many patients carry large intragenic deletions (175,176). DOCK8 deficiency affects generation and persistence of memory T cells (177) and impairs migration of dendritic cells during immune responses (178). Furthermore, studies in mice suggest that DOCK8 deficiency may also cripple germinal center formation and generation of long-lived plasma cells (179). Loss of naïve T cells is associated with markedly reduced levels of TRECs in young infants, suggesting that the disease might also be identified through newborn screening for SCID (180). In most patients, the clinical course is dismal, however, immune reconstitution can be achieved by HSCT (181,182).

**80.2.5.5 Calcium Flux Defects.** TCR cross-linking results in downstream signaling events leading to activation of phospholipase C $\gamma$ , generation of inositol 1,4,5-triphosphate and release of endoplasmic Ca<sup>2+</sup> stores.

This is followed by influx of extracellular Ca<sup>2+</sup> through calcium-release activated calcium (CRAC) channel.

Autosomal recessive mutations in the *ORAI1* gene were identified in a family with combined immunodeficiency associated with severe impairment of calcium influx and of NFAT-dependent gene activation (183–185). The ORAI1 protein was then found to be an essential component of the CRAC channel (186). The stromal interacting molecule 1 (STIM1) is located in the endoplasmic reticulum and senses release of Ca<sup>2+</sup> from endoplasmic stores. Through its C-terminal domain, STIM1 interacts with and activates ORAI1, thereby promoting opening of CRAC channels. Following the discovery of *ORAI1* mutations, genetic defects of *STIM1* were also identified in patients with combined immunodeficiency and calcium flux defects (187).

Deficiencies of ORAI1 and of STIM1 in humans are associated with a unique clinical phenotype that is characterized by immunodeficiency, nonprogressive muscular hypotonia and anhidrotic ectodermal dysplasia (with a defect in dental enamel calcification and inability to sweat), as well as, in the case of STIM1 deficiency, autoimmunity and lymphoproliferative disease (184,187–189). In one case, STIM1 deficiency was associated with early-onset and fatal Kaposi syndrome (190). Patients with ORAI1 or STIM1 deficiency have a normal number of circulating T, B and NK lymphocytes; however, there is an increased proportion of T cells expressing activation markers. Furthermore, there is defective proliferation to mitogens and impaired induction of the nuclear factor of activated T cells (NF-AT) transcription factor upon T cell activation (183,184). The latter abnormality accounts for reduced cytokine secretion upon T cell activation. NK cytotoxic activity is also defective (191). Abnormalities of regulatory T cells have been identified in patients with STIM1 deficiency and may contribute to autoimmune manifestations (189).

**80.2.5.6 Defects of CD40 Ligand and CD40.** CD40 ligand (CD40LG) is transiently expressed as a homotrimeric complex on the surface of activated CD4<sup>+</sup> lymphocytes and of platelets. It interacts with CD40, that is constitutively expressed on the membrane of B lymphocytes and of dendritic cells. In addition, CD40 is also expressed on the surface of activated endothelial and epithelial cells. CD40LG/CD40 interaction during cross talk between T and B lymphocytes is one of the signals that promote B cell activation and proliferation. Along with appropriate cytokines, it induces class switch recombination and somatic hypermutation. On the other hand, interaction between T lymphocytes and dendritic cells via CD40LG/CD40 is important for T cell priming and generation of memory T cell responses (192). Accordingly, defects of CD40LG and CD40 result in a combined immunodeficiency, characterized by a normal number of T and B lymphocytes, but impaired antigen-specific T cell responses and an aberrant distribution of immunoglobulin isotypes, with predominance of serum

IgM and severely diminished levels of other Ig isotypes (hyper-IgM phenotype).

The disease is most often seen as an X-linked form, reflecting mutations of the *CD40LG* gene that has been mapped to Xq26 (193,194). The *CD40LG* gene is also known as tumor necrosis factor soluble factor (superfamily), member 5 (TNFSF5). A variety of mutations have been identified in the *CD40LG* gene. The clinical phenotype is marked by infections with bacteria, *Pneumocystis*, CMV, *Parvovirus*, *Cryptosporidium* and *Histoplasma* (195,196). Sclerosing cholangitis secondary to *Cryptosporidium* infection and neuroendocrine or hepatobiliary carcinomas have been reported in a significant number of patients (197,198). Treatment consists of gammaglobulin replacement, the aggressive use of antibiotics (195,196), G-CSF in cases of persistent neutropenia (199) and, in some patients, HSCT (200).

An autosomal recessive variant of the disease is also known, and is due to mutations of *CD40*. Only few cases have been reported (201,202). The clinical and immunological phenotype, and management of the disease are similar to what described above for *CD40LG* deficiency (203).

### 80.3 PRIMARY B-CELL DEFICIENCIES (HUMORAL IMMUNE DEFECTS)

Disorders of humoral immunity, or antibody deficiency disorders, can be of infantile or late onset, and may involve absence of all classes or only specific classes of immunoglobulins, with or without the absence of B cells of different maturation stages. The primary clinical manifestation in all of these disorders is recurrent infections with common pyogenic bacteria such as *Haemophilus influenzae* and *Streptococcus pneumoniae*. The response to most viral, fungal, or mycobacterial infections may be relatively normal, reflecting the retention of normal T-cell immunity. However, in patients with common variable immunodeficiency, diarrhea, chronic pulmonary disease, and autoimmune phenomena are more prominent features, and variable degrees of cellular immune defects may be present. Treatment of most humoral deficiencies consists of regular infusions of immunoglobulins via intravenous or subcutaneous route, which results in marked reduction of bacterial infections.

While the most common form of agammaglobulinemia is inherited as an X-linked recessive disorder (Bruton agammaglobulinemia), several rarer autosomal recessive forms, have also been identified, and in most cases their genetic basis has been defined. A recent comprehensive review on primary B cell immunodeficiencies was published by Conley et al. (204).

#### 80.3.1 X-Linked Agammaglobulinemia

Infantile X-linked (Bruton) agammaglobulinemia is the classical example of an isolated B-cell defect

(205), and was first described in 1952, when Colonel Bruton reported the case of an 8-year-old boy with recurrent pneumococcal infections, who lacked the  $\gamma$ -globulin fraction on serum electrophoresis (206). The clinical course of these patients is such that they are usually healthy during the first months of life, probably reflecting the presence of adequate amounts of placentally transferred maternal IgG. They then begin to suffer from multiple recurrent infections, usually with pyogenic organisms, while infections with most viruses and gram-negative bacteria are not strikingly increased. Upper and lower respiratory tract and skin infections are particularly common, however, invasive infections including sepsis and meningitis may also occur. Although the use of antibiotics has lessened mortality from acute infections, without immunoglobulin replacement therapy, chronic pulmonary disease, bronchiectasis, and respiratory failure will develop in these patients. These children are more susceptible to infection with enteroviruses, particularly ECHO and poliomyelitis viruses. Paralytic polio can follow administration of live polio vaccine, and a dermatomyositis-like syndrome apparently due to ECHO virus can evolve, even in patients treated with gamma globulin. Mycoplasma and ureaplasma may cause arthritis and meningitis. Intestinal *Giardia lamblia* infection may cause protracted diarrhea and malabsorption. Atypical clinical presentations, including adult onset (207,208), as well as phenotypic variability within families (209,210) have been reported.

Patients with XLA have a severe deficiency of serum IgG, IgM, and IgA, and of circulating B lymphocytes. In the bone marrow, there is a block at the pro-B to pre-B cell stage of differentiation, corresponding to the stage when signaling through the pre-B cell receptor (pre-BCR) would normally occur to promote progression in B cell development. The diagnosis is often suggested by the presence of hypoplastic tonsils and small lymph nodes. Lymph node biopsies show lack of B cell follicle, consistent with the severe reduction of B lymphocytes. T-cell immunity is normal in affected children, and childhood exanthems are handled normally.

Inheritance is that of a classical X-linked disorder. As in any lethal X-linked disorder, one third of patients should reflect new mutations, and therefore a family history may not be obtained.

In 1993, it was demonstrated that XLA is due to mutations of the gene encoding for an intracellular tyrosine kinase, named Bruton's tyrosine kinase, BTK (211,212). The *BTK* gene has been mapped at Xq21.3–22. The BTK protein is expressed throughout B cell differentiation, but is also expressed in platelets and myeloid cells. BTK interacts with various proteins, including phospholipase C- $\gamma$ 2 (PLC- $\gamma$ 2) and the adapter molecule BLNK. Activation of pre-B cells through the pre-BCR, and of B cells through the BCR results in tyrosine phosphorylation of BTK and calcium flux (213).

More than 600 mutations have been described in the *BTK* gene (214,215), most of which result in lack of BTK protein expression. Analysis of BTK expression in monocytes or platelets by flow cytometry may help identify patients with XLA (216) and can also be used to identify heterozygous carriers of XLA. However, detection of the BTK protein does not rule out the disease, since the protein may be expressed in patients with missense mutations. One mutation has resulted in selective anti-polysaccharide antibody deficiency (217).

Several patients have been reported with X-linked agammaglobulinemia associated with growth hormone deficiency, originally described by Fleisher et al. (218). At least some of these cases have mutations in *Btk* (219). Similarly, a significant proportion of male patients diagnosed as having common variable agammaglobulinemia (see later) with diminished B-cell numbers have been shown to have mutations in *Btk* and are therefore variants of X-linked agammaglobulinemia (220).

Analysis of BTK expression can also be used for carrier detection. In this case, two populations of monocytes and platelets (expressing and non-expressing BTK) can be detected, reflecting X-chromosome inactivation (221,222); however, this approach may fail to identify carriers of heterozygous missense mutations. Ultimately, diagnosis of XLA is based on demonstration of a *BTK* mutation, and this may also permit carrier detection and prenatal diagnosis.

Treatment of XLA is based on replacement therapy with intravenous immunoglobulins (IVIG) or subcutaneous immunoglobulins.

### 80.3.2 Autosomal Recessive Agammaglobulinemia

*BTK* gene mutations account for approximately 85% of all cases of agammaglobulinemia (204). The remaining 15% affect both males and females. Mutations in autosomal genes that encode for components of the pre-BCR or for proteins of the pre-BCR signaling pathway have been identified in these patients. In particular, six different genes have been identified, each of which, when mutated, causes autosomal recessive agammaglobulinemia:

- $\mu$  heavy chain (*IGHM*) (223), whose mutations are the second most common cause of congenital agammaglobulinemia (224)
- $\lambda 5/14.1$  (*IGLL1*) (225)
- Ig $\alpha$  (*CD79A*) (226,227)
- Ig $\beta$  (*CD79B*) (228)
- BLNK (B-cell linker protein) (229)
- p85 $\alpha$  subunit of PI-3 kinase (230)

In patients with autosomal recessive agammaglobulinemia, the arrest in B cell development is more severe and complete than in patients with XLA (204). However, the clinical manifestations and the treatment are similar.

Infantile agammaglobulinemia must be differentiated from transient hypogammaglobulinemia of infancy. Normally, after birth, the total IgG initially falls precipitously, then slowly begins to rise after a nadir at 5–6 months of age, reflecting the catabolism of maternal IgG counterbalanced by the slow increase in the child's own synthesis of IgG. Simultaneously, IgA and IgM concentrations begin to increase. In transient hypogammaglobulinemia, the expected rises can be delayed until 3 years of age. Sequential measurements demonstrating increases in IgA and IgM, as well as determination of the number of B cells, may help differentiate this temporary disorder from congenital agammaglobulinemia. When present, a family history of maternal male relatives or previous male sibs with persistent agammaglobulinemia, or demonstration of parental consanguinity may aid in the diagnosis, suggesting an X-linked or an autosomal recessive form of congenital agammaglobulinemia.

### 80.3.3 B Cell-intrinsic Defects of Class Switch Recombination

Maturation of antibody responses is marked by class switch recombination (CSR) and by somatic hypermutation (SHM). CSR is the process through which B lymphocytes express immunoglobulin isotypes other than IgM or IgD. In contrast, SHM introduces mutations in the variable regions of rearranged immunoglobulin genes, thereby resulting in improved affinity of antibodies for the respective antigens. Both CSR and SHM occur primarily during the germinal center reaction and require cell membrane as well as soluble signals. Interaction between CD40LG (expressed by activated CD4<sup>+</sup> cells) and CD40 (expressed by B lymphocytes) promotes activation of the NF- $\kappa$ B signaling pathway and induction of the expression of the *AICDA* gene, encoding for Activation-dependent cytidine deaminase (AID). This enzyme deaminates cytidine to uridine at the switch regions located 5' to the heavy chain constant region genes, as well as within the variable regions of immunoglobulin genes. Another enzyme (uracil N-glycosylase, UNG) removes the uridine residues, leaving abasic sites that are cleaved by a DNA endonuclease. DNA repair mechanisms then intervene bringing together two different switch regions, thus allowing CSR.

*AICDA* (231,232) and *UNG* (233) mutations in humans are responsible for autosomal recessive hyper-IgM syndrome, a condition characterized by the presence of increased (or normal) serum levels of IgM with a marked decrease in the other immunoglobulin isotypes. Clinically, patients show increased susceptibility to recurrent pyogenic infections, to autoimmune disease associated with IgM antibodies and to malignant lymphoproliferation of IgM-producing B cells (234). Enlargement of tonsils and lymph nodes is very common. B cells are normal in number but qualitatively abnormal

in that there is a lack of switched and of memory B lymphocytes. SHM is severely compromised in patients with AID deficiency and follows an abnormal pattern in patients with UNG deficiency.

Treatment is based on regular administration of immunoglobulins and prompt recognition and therapy of infections.

### 80.3.4 Common Variable Immunodeficiency

Shortly after Bruton's description of the first case of congenital agammaglobulinemia in 1952, other authors reported the occurrence of severe hypogammaglobulinemia in male and female adults (235,236). Variability of clinical and laboratory findings in such patients was appreciated (237), and for this reason the disease was named "common variable immune deficiency" (CVID). Although the onset may occur at any age, the majority of the patients have a disease onset in late adolescence or adulthood (238,239). Patients presenting at less than 4 years of age are more likely to suffer from some genetically determined immunodeficiency and are excluded from the definition of CVID in several classification. Respiratory tract infections, diarrhea and autoimmune disorders (especially cytopenias) are the most common findings of CVID at presentation. Other clinical manifestations that are common during the course of the disease include: malabsorption (often associated with giardiasis), intestinal nodular lymphoid hyperplasia, lung lymphocytic hyperplasia, thyroid abnormalities, and neoplasia (especially of the gut). Lymphadenopathy and splenomegaly are also common. In addition to low IgG serum levels, CVID patients also have reduced levels of IgA; IgM concentration may be low or within the normal range. B cells are present in most, but not all patients; the majority of them lack CD27<sup>+</sup> memory B cells (239a).

The genetic basis of CVID remains ill-defined. Many cases are sporadic presentations, however, families with an apparent autosomal dominant or, less commonly, an autosomal recessive inheritance have been described. Mutations in the *ICOS* gene, encoding for the inducible co-stimulator molecule expressed by activated T lymphocytes in the germinal center, have been reported in few cases of autosomal recessive CVID (240). Heterozygous and homozygous mutations affecting *TAC1*, which belongs to the TNF receptor family (also known as *TNFRSF13B*), have been reported in 10% of patients with CVID, but also in 1% of healthy controls (241–245). With few exceptions, these are considered disease-predisposing rather than disease-causing mutations. CVID patients with *TAC1* gene abnormalities have a higher risk to develop autoimmunity and splenomegaly. Biallelic mutations in the gene encoding another TNF-R family member, *BAFF-R*, have been described in two siblings from a single family (246). In a few CVID patients,

autosomal recessive mutations have been identified in the genes encoding CD19 (247,248) or another component of the CD19 complex, CD81 (249). Single cases of CD20 deficiency (250) and of CD21 deficiency (251) have been described. Finally, two siblings with hypogammaglobulinemia, poor antibody response to T-dependent antigens, T cell dysfunction, and EBV viremia have been recently reported to carry homozygous mutations in the CD27 gene (252). With the exception of *TAC1* variants, all other disease-causing mutations reported above represent rare causes of CVID. Therefore, the genetic basis of the disease remains undefined in the majority of CVID patients. Association with certain HLA haplotypes has been reported (253–256), but the precise gene involved remains unknown. Recent genome-wide association studies have suggested that some copy number variants are more common in CVID (257). Treatment is based on regular administration of immunoglobulins, antibiotic prophylaxis, and use of immunosuppressive or immunomodulatory drugs in patients with autoimmune manifestations. Surveillance against lymphoma and tumors of the gastrointestinal tract should be also performed.

### 80.3.5 Selective IgA Deficiency

Selective IgA deficiency is the most commonly observed immunodeficiency, with an incidence of 0.1%–0.2% in normal blood donors, although it is rare in Orientals. There is a 14-fold increase in the incidence of IgA deficiency among the first-degree relatives of these normal individuals (258,259). In most such individuals, this deficiency is not associated with any disease. A high incidence of IgA deficiency has also been reported in patients with recurrent infections, autoimmune disorders such as rheumatoid arthritis, systemic lupus erythematosus, malabsorption syndrome (sometimes with gluten sensitivity), childhood asthma, and other atopic diseases. Normal blood donors are by definition healthy adults, and therefore individuals with an increased predisposition to infection beginning in childhood would not be included. Familial occurrence of IgA deficiency has been reported on numerous occasions, with patterns of inheritance consistent with both an autosomal dominant and autosomal recessive mode of inheritance. Association with MHC haplotypes has been reported (260–262). Discordance of IgA-deficient identical twins has been described, indicating a strong environmental component for the determination of serum IgA. In several cases, evolution of selective IgA deficiency toward CVID has been reported; furthermore, coexistence of CVID and IgA deficiency in the same family is also possible.

IgA deficiency is also found in one third to one half of individuals with a wide variety of chromosome 18 abnormalities and is typically present in patients with ataxia telangiectasia (see later). As a note of warning, IgA-deficient individuals often have antibodies to IgA

and can have a severe transfusion reaction when given normal whole blood, plasma, or preparation of immunoglobulins containing significant amounts of IgA.

### 80.3.6 Selective IgG Subclass Deficiency

Selective deficiency of specific IgG subclasses due to either regulatory or structural mutations could, in theory, lead to inability to cope with a limited spectrum of infectious agents. This hypothesis is based on the observation that certain antibody activities occur largely within specific subclasses of IgG. However, compensatory mechanisms often exist, such that IgG subclass deficiency per se may not represent a clinically significant immunodeficiency, unless impaired production of specific antibodies are demonstrated, in association with recurrent sinopulmonary infections. Deletions and duplications at the duplications at the Ig heavy chain locus on chromosome 14 have been reported in 5%–10% of Caucasian subjects, and may contribute to IgG subclass deficiency (263); however, in most cases, there are no major structural changes of the locus. Alternatively, the condition may reflect impaired regulation of the immune system, including primary imbalance of T-cell subsets (264). The subject has been reviewed (265,266).

## 80.4 IMMUNODEFICIENCIES WITH IMMUNE DYSREGULATION

So far, we have reviewed disorders in which defects in the development and/or function of T and/or B lymphocytes cause immunodeficiency with increased susceptibility to infections. In other conditions, however, abnormalities of lymphocyte function cause immune dysregulation, with increased risk to develop autoimmune diseases and/or inability to extinguish immune responses, leading to uncontrolled inflammation and autoimmunity.

### 80.4.1 Autoimmune Polyendocrinopathy–Candidiasis–Ectodermal Dystrophy

Autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome represents the prototypic disorder of impairment in the mechanisms that govern T cell central tolerance. The disease is due to mutations in the gene *AIRE* (autoimmune regulator) (267,268) that encodes a transcription factor expressed by thymic medullary epithelial cells where it induces expression of tissue-specific antigens that are presented in association with MHC class II molecules to nascent T lymphocytes (269). High-affinity recognition of self-peptides leads to deletion of self-reactive T cells. APECED is inherited as an autosomal recessive trait and is characterized by autoantibodies to multiple endocrine organs, ectodermal dysplasia, susceptibility to candidiasis, an increased incidence of oral squamous cell carcinoma, and fulminant autoimmune hepatitis. It is

clinically heterogeneous, and there are numerous different mutations in the gene.

### 80.4.2 Immune Dysregulation–Polyendocrinopathy–Enteropathy–X-linked Syndrome

Treg lymphocytes play a critical role in the periphery by suppressing self-reactive T lymphocytes that have escaped central tolerance (270). Generation of Treg cells is under control of another transcription factor, FOXP3 that includes a forkhead domain. Mutation of this gene, which maps on the X-chromosome (Xp11.23) cause a severe X-linked syndrome combining autoimmunity with immune dysregulation (271–273). Clinically the syndrome, called immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX), is characterized by skin manifestations (up to generalized erythroderma), intractable enteropathy, autoimmunity (often including early-onset diabetes mellitus), other endocrine disorders, and cytopenias. Lymphoproliferation is also very common. The onset is typically in the first month of life, but delayed presentations have been also observed. A similar phenotype has been observed in the scurfy mouse (274), a mouse model with a spontaneous mutation in the ortholog gene. Patients with IPEX require immune suppression, but the only definitive treatment currently available is allogeneic HSCT (275).

### 80.4.3 Immune Dysregulation due to Defects of IL-2-mediated Signaling

Treg cells express the high-affinity IL-2 receptor, and signaling through IL-2 is important to maintain high levels of expression of FOXP3. Autosomal recessive mutations in the *CD25* gene, which encodes for the  $\alpha$  chain of the IL-2R, cause immune dysregulation associated with lymphoproliferation (276,277).

Interaction of IL-2 with its high-affinity receptor activates the JAK–STAT pathway. An important role in this process is played by the transcription factor STAT5B, which is also activated in response to other receptors, including the growth hormone receptor (GHR). Biallelic mutations of the *STAT5B* gene in humans cause an immunodeficiency characterized by susceptibility to infections, growth failure with growth hormone insensitivity, and autoimmunity (278,279).

### 80.4.4 Autosomal Lymphoproliferative Syndrome

Another syndrome with excessive lymphoproliferation is due to diminished apoptosis of lymphocytes and is associated with autoimmune phenomena (e.g. hemolytic anemia, thrombocytopenia), marked lymphadenopathy, and splenomegaly. The disease is characterized by an

expansion of CD3<sup>+</sup> CD4<sup>-</sup> CD8<sup>-</sup> double-negative (DN) T cells that express the  $\alpha\beta$  form of the T-cell receptor (280). Most patients are heterozygous for a mutation of apoptosis-inducing FAS (CD95, APO-1) (281,282), although homozygotes with a more severe disease have been reported. There is variable penetrance, partly dependent on the site of the mutation in the gene (283,284). Patients with FAS defects have a higher risk of developing lymphoma.

Other rare causes of ALPS are represented by mutations of FAS ligand (285,285a), FADD (286), caspase 8 (287) and caspase 10 (288), all of which are involved in the FAS-mediated signaling pathway leading to apoptosis.

The apoptosis of chronically activated T lymphocytes can also be induced through FAS-independent mechanism involving the release of cytochrome *c* and the activation of caspase 9. This “intrinsic” (or mitochondrial) pathway of apoptosis is elicited in response to cell damage and cytokine (e.g. IL-2) deprivation. Gain-of-function mutations of *N-RAS* may disrupt this pathway and cause ALPS (289). Somatic mutations of *K-RAS* may also cause ALPS (290,291), but this variant does not result in an increase in the number of DN T lymphocytes.

#### 80.4.5 Defects of Lymphocyte Cytotoxicity

Cytotoxic T lymphocytes and NK cells play an essential role in the defense against viruses, by promoting killing of virus-infected cells through two key mechanisms: FAS-mediated apoptosis and release of cytotoxic molecules such as granzyme through pores in the membrane that are generated by perforin. Defects in the cytolytic machinery of cytotoxic T cells and NK lymphocytes cause increased susceptibility to severe viral infections, especially to Epstein-Barr virus (EBV), but also to cytomegalovirus (CMV) and other viruses. Furthermore, persistence of the virus may promote continuous activation of the immune system, with release of inflammatory cytokines (especially IFN- $\gamma$ ) that cause tissue damage. Several genetic defects have been identified in humans that compromise lymphocyte-mediated cytotoxicity.

#### 80.4.6 Familial Hemophagocytic Lymphohistiocytosis

Familial hemophagocytic lymphohistiocytosis (FHL) includes several genetically determined disorders of lymphocyte cytotoxicity. In patients with FHL, the inability to clear viral infections causes persistent activation of CD8<sup>+</sup> and NK lymphocytes, and results in high levels of IFN- $\gamma$  and of pro-inflammatory cytokines (TNF $\alpha$ , IL-6) (292). Clinical features of FHL include episodes of high fever, pancytopenia, liver and spleen enlargement and neurological signs. At present, five

different forms of FHL have been identified, and the defective gene is known in four of them; in all cases, the disease is inherited as an autosomal recessive trait. Perforin deficiency (also known as FHL2) accounts for approximately 30% of all cases of FHL (293). It is caused by mutations of the *PRF1* gene, which prevent expression and/or correct assembly of perforin multimers that form pores through which cytolytic enzymes are released into target cells.

In other forms of FHL, the genetic defect interferes with the formation and intracellular trafficking of cytolytic granules. This is an ordered process through which cytoskeleton rearrangement guides transport of endosomal cytolytic granules to the lytic synapse that forms between cytotoxic lymphocytes (or NK cells) on one hand, and the target cell on the other. During this process, the small GTPase Rab27a promotes docking of the lytic granules, Munc 13-4 induces priming of the cytolytic granules, and syntaxin-11 and Munc 18-2 (also known as syntaxin-binding protein) promote the fusion of the lytic granules with the cell membrane. Mutations of the *UNC13D* gene, encoding for Munc13-4, cause FHL3 (294,295), the most common form of FHL (30–40% of all cases). FHL4 is caused by mutations of the *STX11* gene, encoding for syntaxin 11 (296). FHL5 has been recently shown to be caused by mutations of the *STXBP2* gene, encoding for the Munc18-2 protein. Both missense and nonsense mutations in this gene have been identified (297,298), and there is evidence of a genotype–phenotype correlation, with severe mutations being associated with early onset and more severe clinical course (297). Finally, mutations of the *ITK* gene, encoding for the IL-2-inducible tyrosine kinase that modulated the strength of signaling through the TCR, have been associated with increased risk of EBV-driven lymphoproliferative disease, Hodgkin lymphoma, hypogammaglobulinemia and hemophagocytic lymphohistiocytosis. The condition is inherited as an autosomal recessive trait and is also characterized by a reduced number of natural killer T (NKT) cells and of naïve CD4<sup>+</sup> lymphocytes (299).

FHL is fatal in the absence of treatment, which is based on the prompt recognition and therapy of underlying infections, use of potent immunosuppressive drugs and chemotherapy (300). The only curative approach is represented by HSCT, and excellent results have been obtained with use of reduced-intensity conditioning regimens (301).

In some other disorders, defective lymphocyte-mediated cytotoxicity is associated with extra-immune manifestations related to defective intracellular trafficking of other proteins. In particular, mutations of the *RAB27A* gene cause Griscelli syndrome type 2, an autosomal recessive disease in which features of FHL associate with partial albinism, with clumping of pigment in hairshafts (302).

Chediak-Higashi syndrome associates features of FHL with partial albinism, peripheral neuropathy and

the presence of giant lysosomes, which can be readily identified in leukocytes. The disease is due to mutations of the *CHS1* gene, also known as *LYST* (lysosomal trafficking regulator), which encodes for a protein involved in the sorting of proteins to secretory endosomes (303,304). This defect affects not only cytotoxic lymphocytes (accounting for FHL-like clinical features), but also melanocytes, which are unable to transfer melanin to keratinocytes and other epithelial cells, thus accounting for albinism. Neutropenia is often present and may contribute to increased susceptibility to bacterial infections.

Hermansky–Pudlak syndrome type 2 is an autosomal recessive disease caused by mutations of the *AP3B1* gene, which encodes for the  $\beta$  component of the AP-3 complex, involved in sorting of transmembrane proteins to secretory lysosomes (305). Clinical manifestations include partial albinism, nystagmus, prolonged bleeding, recurrent bacterial and viral infections, and increased risk of hemophagocytic lymphohistiocytosis (306). Pigmentary abnormalities, neutropenia, platelet dysfunction (with absence of dense granules and reduced platelet aggregation) and defective cytotoxic activity account for the clinical manifestations of the disease.

### 80.4.7 X-Linked Lymphoproliferative Syndrome

An X-linked recessive lymphoproliferative syndrome has been described in several kindreds (307). In most cases, development of lymphoproliferative disease reflects inability to contain infection with EBV. Two genetically distinct forms of the disease are known. Males with X-linked lymphoproliferative disease type 1 (XLP1) are uniquely susceptible to life-threatening complications of EBV infections, including fatal infectious mononucleosis, hemophagocytic lymphohistiocytosis, aplastic anemia, and EBV-related lymphoma. A proportion of the males who survive primary EBV infection, develop hypogammaglobulinemia (307) and may be misdiagnosed as having CVID (308). XLP1 is due to mutations of the *SH2D1A* gene that encodes for an SH2 domain-containing adapter molecule, also known as SAP (SLAM-associated protein) (309,310). Various molecules of the SLAM family are expressed on the surface of cytotoxic T lymphocytes and NK cells. Through SAP, they trigger activatory signaling pathways that ultimately lead to the killing of EBV-infected cells (311). In the absence of SAP, these activatory pathways are inhibited, and EBV infection remains uncontrolled. SAP is also important for the function of follicular helper T cells that promote maturation of antibody responses (312). Consistent with this, XLP1 males often develop hypogammaglobulinemia with lack of memory B lymphocytes. Finally, XLP1 is also associated with impaired development of NKT lymphocytes (313). The condition can be corrected by transplantation of bone marrow (314) and by cord blood stem cell infusion (315).

A minority of patients with XLP carry defects in another gene (*BIRC4*) that encodes for the X-linked inhibitor of apoptosis (316). Consistent with this, lymphocytes from patients with this disease (XLP2) show increased susceptibility to activation-induced apoptosis. As compared to XLP1, patients with XLP2 have a higher incidence of HLH (with or without EBV infection), but do not show increased risk of lymphoma. Hypogammaglobulinemia is often present (317,318).

## 80.5 IMMUNODEFICIENCY SYNDROMES

A number of congenital immunodeficiencies are also characterized by extra-immune clinical manifestations, reflecting a broader expression of the gene whose defects are responsible for the disease. Here, we will review those immunodeficiency syndromes that also involve defects of lymphoid development and/or function.

### 80.5.1 Immunodeficiency with Hyper-IgE (Job's Syndrome)

In 1972, Buckley described a novel immunodeficiency syndrome characterized by recurrent staphylococcal abscesses, markedly elevated serum IgE, coarse facies, and a history of pruritic dermatitis (319). The original patients were fair-skinned, red-headed girls with eczema and recurrent “cold” staphylococcal abscesses of the skin, subcutaneous tissue, lymph nodes, lung, liver, and abdominal cavity. The severe recurrent staphylococcal abscesses often begin in infancy and involve skin, lungs, joints, and other sites, with virtually universal development of pneumatocèles. The abscesses are tender and warm, although systemic toxicity is less than expected. Occurrence of boils in these patients has also led to use the eponym of Job's syndrome (320). Infections with other bacterial and fungal agents can occur. All patients at some time have pruritic dermatitis, but the distribution and characteristics of the lesion are different from classical atopic dermatitis. Eosinophilia has been a consistent finding. Abnormalities of teeth, bones, and connective tissue have been described (321). A neutrophil or monocyte chemotactic defect is not a necessary part of this syndrome and is an inconstant finding. Variable abnormalities in cellular immunity are seen, manifested usually as skin test anergy and diminished proliferation in vitro to antigens and allogeneic cells. Both males and females have been affected with equal frequency, and members of succeeding generations have also been affected, consistent with an autosomal dominant mode of inheritance. Sporadic presentations are also common. This multisystem disorder is due to heterozygous dominant-negative mutations of the gene encoding the transcription factor STAT3 (322,323). Most of the HIES-causing mutations of STAT3 are missense or in-frame deletions in the SH2 or DNA-binding domains. The mutations tested are intrinsically loss-of-function but exert inhibit STAT3

function in a dominant-negative manner in heterozygous cells (322). STAT3 is directly involved in signaling from a multitude of hematological and extra-hematological receptors, including those using the common  $\beta$  chain gp130. STAT3 is required for the development of IL-17 CD4<sup>+</sup> T cell-mediated responses, due to the requirement of STAT3 for cellular responses to IL-6, IL-21 and IL-23, which induce development of IL-17-producing T cells (Th17). The development of Th17 cells is thus profoundly impaired in patients with HIES (324–326). IL-17 is essential for the defense against *Candida*, and Th17 cytokines induce production of antimicrobial peptides by bronchial epithelial cells (327), thus explaining the increased occurrence of *Candida* and staphylococcal infections in patients with HIES. The molecular mechanisms underlying elevated IgE levels in patients with HIES remain unknown.

Autosomal recessive forms of HIES have been also described. DOCK8 deficiency is associated with severe abnormalities of lymphocyte function, resulting in a combined immunodeficiency (see above).

A patient with autosomal recessive HIES due to deficiency of TYK2 (a member of the JAK family of tyrosine kinases that activate STAT proteins) has been also described (328). The clinical and immunological phenotype was characterized by atopy, susceptibility to cutaneous staphylococcal diseases and high serum concentrations of IgE. This patient was also susceptible to intramacrophagic bacteria, such as BCG and *Salmonella* in particular, and viruses, which are not typically observed in patients with HIES due to *STAT3* mutations. Recently, another Turkish patient with TYK2 deficiency has been described, who suffered from disseminated BCG infection, neurobrucellosis, and cutaneous herpes zoster infection, in the absence of atopy, elevated IgE or staphylococcal infections (329). Thus, the clinical and immunological phenotype of TYK2 deficiency remain controversial and may not necessarily be part of the HIES spectrum.

### 80.5.2 DiGeorge Syndrome

DiGeorge syndrome is a congenital disorder in which there are abnormalities of structures derived from the third and fourth pharyngeal pouches, including the thymus and parathyroids. The absence of the parathyroid glands often results in neonatal tetany. Patients have characteristic facies with micrognathia, low-set malformed “pixie” ears, cleft palate, short philtrum of the lip, and antimongoloid slant of the eyes. There are often associated abnormalities of the aortic arch (commonly truncus arteriosus communis), and the cardiac manifestations may overshadow the other features of this disorder (330). Although the thymic shadow is absent radiographically, some ectopic thymic tissue may be identified at autopsy. This variability in the degree of thymic hypoplasia presumably explains the variability

in the extent of the T-cell defect in different patients. Patients are not usually profoundly lymphopenic, but cellular immune function is usually diminished, with reduced number of T cells and impaired response to mitogens or antigens. These patients classically have multiple *Candida* and viral infections, while antibody function is usually normal. B-cell percentages are elevated. Therapy is difficult to evaluate critically since, in some patients, immune function gradually improves, presumably reflecting growth of thymic remnants. However, approximately 1% of the patients with DiGeorge syndrome show extreme lymphopenia and present with SCID-like clinical features. For these patients with “complete DiGeorge syndrome,” treatment is based on thymus transplantation (331,332).

Many cases of DiGeorge syndrome show a deletion of 22q11.2 (333), either sporadic or as a result of an unbalanced translocation, often familial. It has become clear that DiGeorge syndrome is a developmental field defect associated with a contiguous gene deletion of variable size, sometimes visible by cytogenetic techniques but more generally detectable by fluorescent in situ hybridization using probes from 22q11.2 (334,335). Smaller deletions result in the velocardiofacial syndrome or only in the conotruncal defects of the heart. Other cases have a deletion of chromosome 10p14–p13 (336–338). Numerous genes have been isolated from the deleted region in chromosome 22, but none has been definitively shown to be responsible for the syndrome (339), although a possible candidate gene is *TBX1* since its deletion causes abnormalities in mice that resemble those in affected humans (340). The mechanisms of the various-sized deletions have been shown to be due to unequal crossing over at regions of low-copy repeats (341–343).

### 80.5.3 Wiskott–Aldrich Syndrome

The Wiskott–Aldrich syndrome is a rare X-linked recessive disorder characterized by thrombocytopenia, eczema, and recurrent infections, usually with polysaccharide-containing pyogenic bacteria, but also with other bacteria, viruses, and fungi. If untreated, the majority of patients die in childhood (344). The most common cause of death is infection, commonly of the respiratory system, followed by bleeding, most often into the central nervous system. Lymphoid malignancies occur frequently (over 12% of patients). Thrombocytopenia is usually observed at birth and is often exacerbated during periods of infection. Platelets are small in size, respond abnormally to aggregating agents and have a diminished half-life. Splenectomy usually results in increase in platelet number and size, a normal half-life of autologous platelets, and a normal aggregating response to epinephrine (345), but is associated with an increased risk of fatal bacterial infections. The eczema usually appears by 1 year of age and may be superinfected. The recurrent infections are associated with variable defects

in humoral and cellular immunity. Immunoglobulins are both catabolized and synthesized more rapidly than normal, and the most common resulting pattern of serum immunoglobulin is elevated serum IgA and IgE with low IgM. Serum isohemagglutinins are absent or very low. Patients are unable to mount an antibody response to polysaccharide antigens (e.g. pneumococcal vaccine or A and B blood groups) but can generate relatively normal antibody responses to protein antigens. B cells are normal in number, but *in vitro* synthesis of immunoglobulin is variably abnormal, depending on the stimulant utilized. Cellular immunity can also be abnormal. Patients are generally anergic to skin test antigens, and T lymphocytes do not proliferate normally *in vitro* in response to antigens or allogeneic cells. Autoimmune phenomena (e.g. hemolytic anemia) are common (346).

Wiskott–Aldrich syndrome has a crude incidence of approximately four per one million male births, however under-reporting is likely. The WAS gene has been mapped to Xp11.22–11.23 (347), and has then been cloned (348). The WAS protein (WASp) is involved in cytoskeleton reorganization, and mediated actin polymerization in response to activating signals (349). In particular, the WASp GTPase binding domain (GBD) interacts with Cdc42, thus linking cellular activation to WASp recruitment. Furthermore, the C-terminal domain of WASp binds to the Arp2/3 complex, thereby facilitating actin polymerization. WASp also interacts with tyrosine kinases involved in mediating growth factor signals (349,350). The N-terminal domain of WASp interacts with the WASp-interacting protein (WIP), and this interaction stabilizes WASp. A wide diversity of WAS mutations has been observed in affected patients, with some genotype/phenotype correlation (351). In particular, missense mutations in exons 1 and 2 of the WAS gene that affect interaction with WIP are associated with reduced, but detectable, levels of WASp and often result in a milder phenotype, with isolated thrombocytopenia (352). In some families, the thrombocytopenia may even be intermittent (353).

Patients with WAS should receive immunoglobulin replacement therapy and antimicrobial prophylaxis. Definitive treatment is based on HSCT, and improved outcome has been reported in recent years (354).

Activating mutations in the GBD domain of WASp lead to a very distinct phenotype, characterized by congenital X-linked neutropenia and myelodysplasia (355,356).

Mutations of the *WIPF1* gene, encoding for WIP, result in an immunodeficiency syndrome that resembles WAS, but is inherited as an autosomal recessive trait (356a). In this disease, lack of WIP results in impaired stability, and hence decreased levels, of WASp.

## 80.5.4 Immunodeficiencies with Associated Chromosome Breakage

**80.5.4.1 Ataxia Telangiectasia.** Ataxia telangiectasia (AT) is characterized clinically by the occurrence of

progressive cerebellar ataxia, ocular and cutaneous telangiectases, frequent and severe sinopulmonary infections, a very high incidence of neoplasia, and variable abnormalities of both cellular and humoral immunity (357). Although initial investigations indicated that this is a genetically and clinically heterogeneous group of disorders with between five and nine complementation groups (358), it is now clear that all patients with classical AT have mutations in the same gene (see later).

The disease is usually first recognized as the child attempts to walk. The ataxia and dysarthria are progressive, and additional neurologic abnormalities develop, including choreoathetosis, myoclonic jerks, nystagmus, and oculomotor apraxia. Increased infections become evident during the first year of life but are not usually prominent until 3–8 years of age. The telangiectases usually appear between 2 and 8 years of age. Progeric changes develop in the adult and include premature graying of the hair, early loss of subcutaneous tissue, sclerodermoid changes, vitiligo, and café au lait spots.

The most prominent and consistent immunologic abnormality is absent or deficient serum and secretory IgA and serum IgE and the presence of a low-molecular-weight IgM. The latter may result in factitiously high IgM measurements by radial immunodiffusion. Autoantibodies are common. Diminished *in vitro* cellular immune responses are also common, and the thymus often has a fetal-like histologic pattern. Endocrine abnormalities involving several organs are also frequent. Some patients have hyperinsulinism, insulin resistance, and hyperglycemia. Many patients show hypogonadism with absent or hypoplastic ovaries in females. Hepatic abnormalities also occur, and elevated  $\alpha$ -fetoprotein is common. Patients usually die before early adulthood as a result of the recurrent respiratory infections or a lymphoproliferative neoplasm.

AT is one of the chromosome instability syndromes (359), and patients' cells develop chromosome abnormalities at high frequency. The chromosome abnormalities typically involve the translocation of the long arm of chromosome 14 with the breakpoint at 14q11–12 and 14q32, as well as chromosome 7 (7p13 and 7q35). These positions correspond to the loci for immunoglobulin heavy chains and the various genes for the T-cell receptor. In addition to showing an increased rate of "spontaneous" chromosome rearrangements, cells from patients with AT are also more sensitive to ionizing radiation and radiomimetic chemicals. *In vivo*, patients react adversely to standard radiotherapy and may die in the course of treatment. The gene (*ATM*) has been cloned, and disease-causing mutations have been identified in patients with AT (360,361). The gene product is a large phosphoprotein that is a member of a family of genes involved in response to DNA-damaging agents and that shares a PI3-kinase domain (362) and exhibits kinase activity (363). It also plays a role in immunoglobulin class switch recombination (364).

AT has an incidence of approximately 25 per million and appears to be inherited as an autosomal recessive. The disorder occurs at higher frequency among Moroccan Jews. Obligate heterozygotes have been reported to be at increased risk for development of neoplasia (365,366). Detection of heterozygotes is now available by mutation analysis. Numerous different mutations of all types have been reported (367,368). Autoimmunity and oculocutaneous telangiectases have been reported in some heterozygotes.

**80.5.4.2 Nijmegen Breakage Syndrome.** The Nijmegen breakage syndrome (NBS) is an autosomal recessive disorder characterized by chromosomal instability, microcephaly, immunodeficiency, increased incidence of cancer and sensitivity to ionizing radiation. The patients show no neurologic abnormalities or telangiectasia. The disease was mapped to 8q21 (369), and then the gene was cloned by positional cloning (370) and by isolating a member (p95) of a DNA repair complex (hMre11/hRad50) mapping to the same region (371). The NBS gene encodes for a protein nibrin, and multiple mutations have been identified.

**80.5.4.3 Ligase 4 Deficiency.** DNA ligase 4 is another DNA repair protein and is involved in NHEJ. Mutations of the *LIG4* gene are associated with a spectrum of clinical manifestations that include microcephaly, facial dysmorphisms, bone marrow failure, growth and developmental delay, cellular radiosensitivity leading to increased risk of leukemia and other malignancies, and a variable degree of immunodeficiency (122,372). In some cases, impaired NHEJ activity causes severe defects of V(D)J recombination, and is associated with T- B- SCID (see above).

**80.5.4.4 AT-like Syndrome.** Two families with cerebellar degeneration, immunodeficiency, chromosomal instability, and increased susceptibility to ionizing radiation but no telangiectasia were found to have normal amounts of ATM protein. In light of the similarity to Nijmegen syndrome, genes for other proteins of the hMre11/hRad50 complex were examined, and mutations were identified in the gene *MRE11* (373).

**80.5.4.5 Bloom Syndrome.** Immune defects have also been reported in Bloom syndrome (359), in which chromosomal instability (in the form of increased sister chromatid exchange and homologous chromosomal translocations), an increased rate of infection, decreased IgM, and diminished delayed hypersensitivity have been described. The gene responsible, termed *BLM*, is a helicase (374). Numerous mutations have been found (375). A syndrome resembling Bloom syndrome, with moderately severe immunodeficiency, has been associated with a mutation in the gene for DNA ligase 1, a DNA repair gene (376). The syndromes are inherited as autosomal recessives.

**80.5.4.6 Immunodeficiency–Centromeric Instability–Facial Anomalies Syndrome.** Another syndrome has been described with immunodeficiency associated with

instability of the centromeric heterochromatin of chromosomes 1, 9, and 16 and with facial anomalies, leading to the acronym ICF syndrome (377). The defect was predicted by studies showing that the affected chromosome regions are hypomethylated (378). About 50% of the patients have been shown to carry mutations in the DNA methyl transferase 3B (*DMMT3B*) gene (379–381). More recently, it has been shown that ICF may also be due to mutations in the zinc-finger- and BTB (bric-a-bric, tram-track, broad complex)-domain-containing 24 (*ZBTB24*) gene (382).

## 80.5.5 Skeletal Abnormalities with Immunodeficiency

Short-limbed dwarfism is associated with more than one form of immunodeficiency (383).

McKusick et al. (384) described the phenotype of 77 Amish children in 53 sibships affected with a form of short-limbed dwarfism associated with cartilage–hair hypoplasia (CHH). In addition to the cartilage and hair abnormalities, affected individuals typically could not extend their elbows, had hyperextensibility of fingers and wrists, and often had a marked sternal deformity. Subsequent studies have demonstrated in vitro immune defects, primarily of cellular but also of humoral immune function (385–387). The syndrome has been described in high frequency in the Finnish population. In some cases, the immunodeficiency is very severe, and resembles SCID (388,389) or may present with Omenn syndrome (390). Patients with CHH are at higher risk of complications after varicella (391) and have an increased incidence of neoplasia, primarily lymphoma and basal cell carcinoma (392). The gene, which has been mapped to 9p13 (393), has been cloned and encodes for the RNA component of the mitochondrial RNA-processing endoribonuclease (RMRP). Mutations affecting coding region and the promoter have been reported, and the type and level of RMRP functional impairment appear to predict the phenotype (394,395). HSCT is effective in the most severe forms of the disease (389).

Schimke immuno-osseous dysplasia is a form of spondyloepiphyseal dysplasia associated with focal glomerulosclerosis and T-cell immunodeficiency (396). The kidney disease is progressive and leads to renal failure. The disease is due to mutations of the *SMARCA1* gene, encoding for a chromatin remodeling protein (397). Incomplete penetrance is associated with environmental and genetic disturbances of gene expression (398).

## 80.5.6 X-linked Hypohidrotic Ectodermal Dysplasia with Immunodeficiency

Hypomorphic mutations of the *IKBKG* gene, encoding for the IKK- $\gamma$  chain, (also known as NF- $\kappa$ B essential regulator, NEMO) result in X-linked EDA-ID (399). Defective NF- $\kappa$ B signaling in males with EDA-ID causes

impaired induction of AID expression in germinal center B cells, and hence results in impaired class switch recombination and a hyper-IgM phenotype. Furthermore, activation of the NF- $\kappa$ B signaling pathway is also important to induce IL-12 production by dendritic cells in response to CD40 stimulation. Defective production of IL-12 and of IFN- $\gamma$  in patients with NEMO mutations causes increased occurrence of mycobacterial infections. In addition, impaired activation of the NF- $\kappa$ B signaling pathway in response to other receptors is responsible for extra-immune manifestations of the disease, including ectodermal dystrophy (with sparse hair, lack of sweat glands, and conical shaped teeth) and, in some patients, lymphedema and osteopetrosis; however, some patients lack manifestations of ectodermal dystrophy (400). Genotype–phenotype correlation has been identified and may explain the complexity of phenotypes (401). Interestingly, null mutations in the same gene cause incontinentia pigmenti in heterozygous females and lead to death in utero in males.

An autosomal dominant form of EDA-ID due to gain-of-function mutation of the *IKBA* gene (encoding for IKB- $\alpha$ ) has been also reported (402,403). The mutation prevents phosphorylation and ubiquitylation-mediated degradation of the protein, and hence results in decreased activation of NF- $\kappa$ B. As compared to NEMO deficiency, the disease is also characterized by defective T cell activation and impaired memory T cell generation.

### 80.5.7 Warts–Hypogammaglobulinemia–Infections–Myelokathexis Syndrome

Immunodeficiency with neutropenia, hypogammaglobulinemia, and extensive warts due to human papilloma virus infection has been shown to be due to mutations in *CXCR4*, the gene for a chemokine receptor (404). The disease follows an autosomal dominant pattern of inheritance and is due to heterozygous nonsense or frameshift mutations that affect the C-terminus of the protein, in a region corresponding to its intracytoplasmic tail. The mutant CXCR4 is expressed at the cell surface, but is not internalized following binding of its ligand CXCL12 (SDF-1). Continuous signaling through the chemokine is therefore delivered. Abnormally sustained CXCR4 signaling causes retention of neutrophils in the bone marrow, where they accumulate and die (myelokathexis).

## 80.6 CONCLUSION

It should be clear from the previous descriptions that, as in other genetic diseases, there is a great deal of heterogeneity in the immunodeficiency disorders. Such heterogeneity can be due to different alleles at the same locus or mutations at different loci resulting in similar phenotypes. Not only is there expected genetic heterogeneity within each general phenotype, but due to the

dependence of many of the symptoms on chance exposure to environmental agents, there is a superimposed significant degree of nongenetic individual variation. In fact, a number of individuals demonstrating immunodeficiency, sometimes indistinguishable from the genetic diseases, develop their conditions as a result of such nongenetic problems as severe viral infections, malignancies, acquired immunodeficiency (e.g. AIDS), or therapy with immunosuppressive and cytotoxic agents. Additionally, a number of inborn errors of metabolism, including storage diseases, urea cycle defects, and organic acidurias and aminoacidurias, as well as several chromosomal disorders, such as those involving chromosome 18 and Down syndrome, demonstrate a variety of immunologic defects leading to increased susceptibility to infection. In great part, the difficulty of accurate classification, with a few notable exceptions, is due to our general lack of understanding of the fundamental molecular defects responsible for many of these conditions. In addition, the dependence of current classification systems on the developmental model of stem cell, B-cell, or T-cell defects, while initially highly useful, has become somewhat naive and, therefore, constricting. The continuous advance in our understanding of the interaction and interdependence of the components of the immune system with each other, and with even more cells and molecules, makes it clear that many modifications of the definitions of immunodeficiencies will come about. No doubt these discoveries, especially as they become increasingly understood on a molecular basis, will bring about the definition of many new defects associated with host defense problems. A number of syndromes that include various forms of immunodeficiency have been described, but the genes responsible have not been elucidated.

It is not only our hope but also our sincere conviction that the increased application of modern biochemical and molecular methodology, including next-generation sequencing, will lead to a clearer understanding of the genetics and the fundamental defects of primary immunodeficiency. It is only with such understanding that more rational counseling and therapy will develop. As so often was true in the past for other fields, a dissection of these genetic defects will inevitably continue to take the field of clinical and cellular immunology from its previous state of descriptive phenomenology into the realm of a proper science, a process that began with our understanding of the immunoglobulins and antibody diversity, as well as the specificity of T cells, and has begun to blossom in the past few years with the molecular definition of several of the primary immunodeficiency diseases.

## Inherited Complement Deficiencies

*Kathleen E Sullivan*

Division of Allergy Immunology, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

This article is a revision of the previous edition article by Alvin E Davis III, Chester A Alper and Fred S Rosen, volume 2, pp 1857–1867, © 2007, Elsevier Ltd.

### 81.1 OVERVIEW

The complement system is a group of 14 proteins comprising the complement cascade and more than 10 regulatory proteins. Seven receptors mediate the biological functions of the complement ligands. Most complement proteins are produced in the liver, although C1q, properdin and C7 are produced predominantly by myeloid cells and factor D is produced by adipocytes and is also known as adipsin (1–5). Many other cells produce small amounts of complement components after pro-inflammatory stimuli and this is thought to magnify the local response (6). The major functions of the complement system are host defense, protection of endothelial surfaces and waste clearance. Each of these functions depends on a slightly different subset of complement proteins and the roles of the specific proteins have been largely elucidated through the study of inborn errors affecting the individual components.

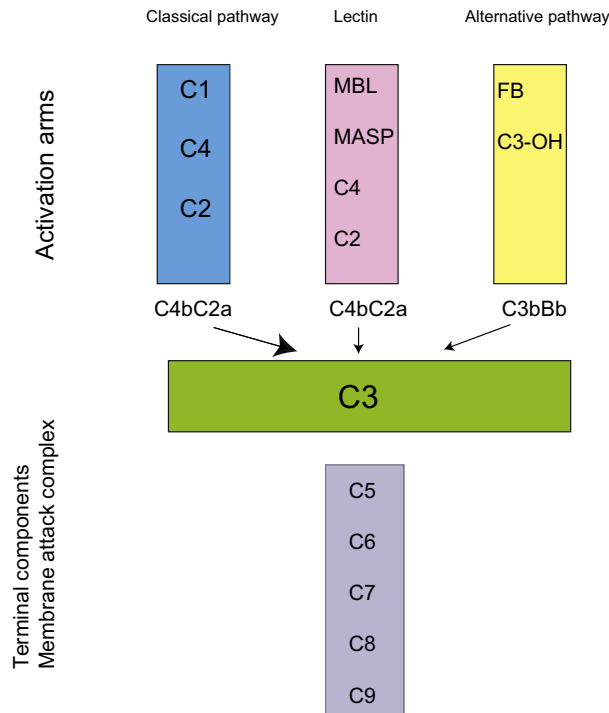

Complement nomenclature follows certain patterns with the classical pathway components generally indicated with an upper case C followed by a number that roughly correlates with the position in the cascade (C4 appears out of order). Alternative pathway members are generally referred to as a “factor” and are designated with a letter (factor B, factor D, factor H). As protein fragments are cleaved off, they are given lower case letter identifiers with the “a” most often designating the smaller fragment (the exception is C2a which is larger than C2b). In some cases, the two fragments can be further cleaved and those smaller fragments are named with additional lower case letters. When a cleavage product is inactive, it is preceded by the letter “i”. Protein complexes with enzymatic activity are termed convertases, i.e. C3 convertase and C5 convertase.

### 81.2 INTRODUCTION TO THE COMPLEMENT SYSTEM

The complement cascade originally evolved to opsonize pathogens and enhance their phagocytosis. The most evolutionarily ancient members of the complement cascade are factor B and C3, the minimal components needed to effect opsonization. As the adaptive immune system evolved, the complement system coevolved such that it now interfaces with nearly all aspects of host defense. A model for the organization of the complement cascade has three activation arms: the classical pathway, the lectin activation pathway and the alternative pathway (Figure 81-1). These three pathways cleave the central protein, C3, and allow it to bind to the nearest surface, usually a pathogen. The lectin activation pathway and the alternative pathway are truly part of the innate immune system but the classical pathway is activated by antigen–antibody complexes and therefore is dependent on the adaptive immune system. C3 constitutes a powerful opsonin and markedly enhances phagocytosis of the pathogen. Cleavage of C3 leads to activation of the terminal components which catalyze the formation of a pore in the membrane.

### 81.3 THE CLASSICAL PATHWAY

The classical pathway is activated primarily by immune complexes. A conformational change occurs when antibody binds antigen, which renders the antibody molecule capable of interacting with C1 (7,8). Only IgG and IgM activate complement and IgM is much more efficient than IgG. In addition, not all isotypes of IgG are equivalent. IgG3 is the most efficient followed by IgG1 and IgG2. IgG4 is not able to activate complement. A single molecule of IgM is sufficient to activate complement while many molecules of IgG bound to a particle are

**FIGURE 81-1** The three activation arms of the complement system. Activation of C3 is important for opsonization and B-cell costimulation. These two major functions of host defense are dependent on C3 and its appropriate activation. The terminal components or membrane attack complex are required for lysis of bacteria.

required to activate complement. In addition to immune complexes, the classical pathway is activated by apoptotic debris and a variety of other proteins and nucleic acids. Once activated, C1, C4 and C2 interact to produce a C3 cleaving enzyme: C4aC2b. Cleavage products resulting from this activation pathway lead to inflammation with erythema (vasodilatation) and edema (vascular leak). Neutrophils become activated and are therefore primed to cross the vascular endothelium to enter into tissues to initiate the attack on the pathogen.

### 81.4 THE ALTERNATIVE PATHWAY

The alternative pathway can, in some circumstances, be activated directly by immune complexes, but it is generally activated through the recognition of oligosaccharide and charge differences common to pathogens. It is a process belonging to of the innate immune system. The alternative pathway exploits the instability of the native C3 molecule and, on activator surfaces, nucleates a complex of C3bBb which cleaves additional C3 to opsonize bacteria and initiate activation of the terminal components. Note that the classical pathway provides an important substrate for the alternative pathway, C3b.

The basis of this pathway is a spontaneous hydrolysis of C3, which occurs in the serum at a rate of 0.2–0.4% per hour (9). The hydrolyzed C3 undergoes a conformational change that facilitates interaction with factor B. When factor B is bound to hydrolyzed C3 can it is cleaved by factor D. C3bBb is the alternative pathway C3 converting enzyme,

which is stabilized by properdin and cleaves additional C3 into C3b and C3a (10). The regulation of this pathway is largely through the effect of factor H on our surfaces. A nonactivator surface (usually our own cells) binds factor H avidly due rich sialic acid residues (11–13). In contrast, on activator surfaces (pathogens), factor H cannot displace factor B from C3b and the alternative pathway activation is allowed to proceed. Activator surfaces are often coated with mannose or *N*-acetyl glucosamine.

### 81.5 THE LECTIN ACTIVATION PATHWAY

The lectin activation pathway is the most recently identified activation arm of the complement cascade and also is a part of the innate immune system. The critical protein, mannose binding lectin (MBL), recognizes oligosaccharides specific to pathogens in a manner similar to that of factor H discussed above (14–16). Mammalian glycoproteins are generally decorated with galactose and sialic acid, not recognized by MBL. In contrast, MBL avidly binds to oligosaccharides associated with bacteria, yeast and parasites such as mannose, *N*-acetyl glucosamine, fucose and glucose (15). MBL also binds to agalactosyl IgG with high affinity (17). This unusual IgG is produced primarily at times of inflammation and this antibody would therefore amplify the complement response at sites of inflammation by activating through both the classical pathway and the lectin activation pathway.

MBL undergoes a conformation change after engaging carbohydrate, leading to activation of MASP2. MASP2 cleaves C4, which binds to a nearby surface as C4b (18). The remaining protein–protein interactions are identical to those in the classical pathway.

### 81.6 THE MEMBRANE ATTACK COMPLEX

Once C3 is cleaved by any of the activation arms described above, it becomes a part of the next enzymatic complex and cleaves C5. The large cleavage fragment of C5 becomes attached to the surface of the pathogen. C5b binds to C6 and C7 and inserts into a lipid membrane (19,20). C5b also binds directly to C8, which then becomes incorporated into the complex. Once this happens, the membrane integrity is compromised. The addition of C9 leads to the formation of true pore (21).

### 81.7 REGULATION OF COMPLEMENT ACTIVATION

The regulators of complement are divided into fluid phase regulators and membrane bound regulators (Table 81-1). C1 inhibitor is perhaps the most clinically important of the regulatory proteins and it is a fluid phase regulator. C1 inhibitor is a serine protease, which inhibits the low-level auto-activation of C1 (Figure 81-2) (22). Immune complex activation of C1 is preserved, although chronic

TABLE 81-1 Complement Regulatory Proteins		
Protein	Localization	Function
C1 inhibitor	Serum	Binds to C1r and C1s and dissociates the C1 complex
C4-binding protein	Serum	Cofactor for factor I cleavage of C4b
Factor I	Serum	Cleaves C3b and C4b
Factor H	Serum	Defines activator surface
S-protein	Serum	Inhibits the insertion of the membrane attack complex into the cell membrane
Decay accelerating factor (DAF)	Ubiquitous-cell membrane	Dissociates both C3 and C5 convertases
Membrane cofactor protein	Hematopoietic cells except erythrocytes	Cofactor for C3b cleavage by factor I
C8 binding protein	Most hematopoietic cells	Binds to C8 and prevents interaction with C9
CD59	Hematopoietic cells, endothelial cells, epithelial cells, glomerular cells	Inhibits the membrane attack complex

Classical pathway activation

**FIGURE 81-2** The regulation of the classical pathway. The classical activation pathway is schematized with the relevant regulatory proteins shown as red ovals.

consumption of downstream proteins limits the efficiency of the classical pathway. C1 inhibitor directly binds to C1s and C1r, leading to dissociation from C1q. C1 inhibitor has a similar function in the lectin activation pathway. Relevant for the clinical manifestations of C1-inhibitor deficiency are its roles in the coagulation pathway. C1 inhibitor has important roles inhibiting factor XII (Hageman factor) and prekallikrein (23,24).

The other important fluid phase regulator is C4 binding protein, which displaces C2a and inhibits cleavage of C3 (25,26). Factor I and factor H regulate the alternative pathway (Figure 81-3; Refs (27–30)). Factor I inactivates

Alternative pathway activators

**FIGURE 81-3** The regulation of the alternative pathway. The alternative activation pathway is schematized with the relevant regulatory proteins shown as a red oval.

C3b and its activity is enhanced by factor H. Factor H identifies nonactivator surfaces through the recognition of mammalian oligosaccharides and displaces Bb from C3b on those surfaces. These two regulators are critical in the prevention of significant spontaneous activation of the alternative pathway. When an activator surface is available, factor H releases Bb and a more intensive and sustained activation of the alternative pathway occurs. Factor I also acts to inhibit C4b from the classical pathway (28,31). Finally, S-protein (distinct from protein S) binds terminal complement components in the fluid phase.

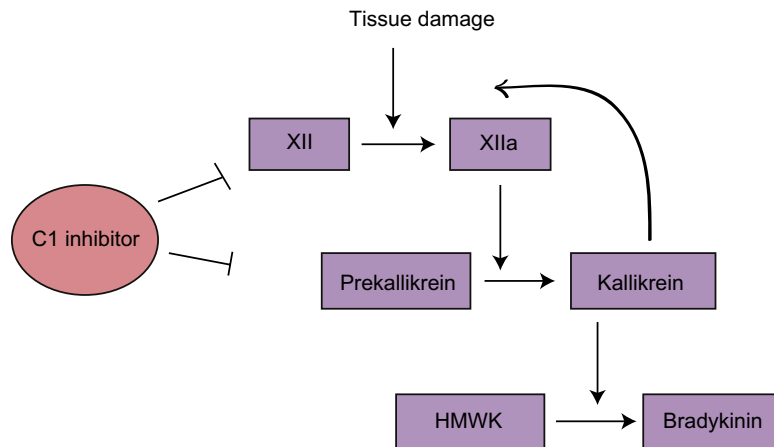

The membrane bound regulators of complement consist of decay accelerating factor (DAF, CD55), membrane cofactor protein (MCP, CD46), C8 binding protein and CD59 (28,32–37). DAF dissociates the C3 convertase and MCP serves as a cofactor for factor I cleavage of C3b and C4b. CD59 inhibits the membrane attack complex and inhibits C9 binding. C8 binding protein functions similarly, but acts via binding to C8. Several receptors terminate complement function and have a regulatory function. CR1 binds C3b and C4b and serves as a cofactor for factor I mediated cleavage. CR2 has a similar role supporting cleavage of C3b (Figure 81-4).

## 81.8 INHERITED COMPLEMENT DEFICIENCIES

### 81.8.1 Overview

Most inherited complement deficiencies are autosomal recessive and except where noted, the mutations are diverse (Table 81-2). Properdin deficiency is X-linked and C1-inhibitor deficiency is autosomal dominant (hemizygous). The defects associated with susceptibility to atypical hemolytic uremic syndrome (aHUS) are particularly diverse, with activating and inactivating mutations, as well as recessive and dominant patterns of inheritance. Inherited complement component disorders are typically associated with a CH50 or AH50

**FIGURE 81-4** The role of C1 inhibitor. C1-inhibitor deficiency compromises the natural inhibitory pathways regulating bradykinin production. Although the complement activation leads to the elaboration of peptides with anaphylatoxic abilities, the main mediator of angioedema is thought to be bradykinin.

**TABLE 81-2** Inherited Complement Deficiencies

Deficiency	Chromosomal Location	Number of Cases Reported	Clinical Features, Diagnostic Strategy
C1q	1p36.12	10–100	SLE, infections, CH50 near zero
C1r/s	12p13	10–100	SLE, infections, CH50 near zero
C4	6p21.3	10–100	SLE, infections, CH50 near zero
C2	6p21.3	Many	SLE, infections, some asymptomatic, CH50 near zero
C3	19p13.3–13.2	10–100	Infections frequent and severe, glomerulonephritis, HUS, CH50 near zero
Factor D	19p13.3	<10	Neisseria, AH50 near zero
Factor B	6p21.3	<10	Neisseria, HUS, AH50, C3 level
Properdin	Xp11.3–11.23	>100	Neisseria, AH50 diminished
C5	9q33	10–100	Neisseria, CH50 near zero
C6	5p13	>100	Neisseria, CH50 near zero
C7	5p13	>100	Neisseria, CH50 near zero
C8	1p32, 9q34.3	>100	Neisseria, CH50 near zero
C9		Many	Neisseria, CH50 diminished
Factor I	4q25	10–100	Neisseria, HUS, C3 may be diminished, many require mutation analysis
Factor H	1q32	10–100	Neisseria, HUS, C3 may be diminished, many require mutation analysis
MCP	1q32	<10	HUS, mutation analysis required
C1 inhibitor	11q12–13.1	Many	Angioedema, C1 antigen and functional levels
CR3/CR4	16p11.2	>100	Leukocyte adhesion deficiency, flow cytometry
CD59	11p13	<10	Hemolysis, flow cytometry

of near zero and identification of the specific deficiency requires a labor intensive serum mixing approach. Specific complement deficiencies are generally defined at this level and mutation analysis is not routinely performed. Exceptions to this are the defects in the regulatory proteins. Because these have a less profound effect on the CH50 and AH50 and they cannot be identified in mixing studies, direct mutation testing is generally the diagnostic maneuver of choice. C1-inhibitor deficiency is an exception to this, as functional testing is widely available and is quite reliable.

## 81.8.2 Defects in Proteins Involved in the Activation of C3

**81.8.2.1 C1 Complex Deficiencies.** C1 is a multi-subunit protein. C1q binds to antibody and C1r and C1s are the enzymatic components, responsible for cleavage. C1q, C1r and C1s deficiencies present nearly uniformly with early onset systemic lupus erythematosus (SLE) (38–40). The SLE is typically severe and arises in childhood. The autoantibody profile is similar to that seen in other SLE patients although anti-dsDNA antibodies may be less

common (41,42). An additional phenotype is recurrent bacterial infections, most often systemic infections with encapsulated organisms. All three deficiencies are inherited in an autosomal recessive pattern.

**81.8.2.2 C4 Deficiency.** There are two distinct genes for C4 termed C4A and C4B. They are highly homologous although C4A binds more avidly to protein while C4B binds more avidly to carbohydrate. Within each C4 locus, there can be deletions or duplications or simple inactivating mutations (43,44). Partial C4 deficiencies are extremely common. One to two percent of the general population and up to 15% of patients with SLE have complete C4A deficiency. One to two percent of the population has complete C4B deficiency and up to 15% of patients with invasive bacterial disease are C4B deficient (45). Complete C4 deficiency due to four inactive alleles is quite rare and the majority of patients with complete C4 deficiency have SLE (46–48). Some complete C4-deficient individuals can be asymptomatic but many have recurrent infections with encapsulated organisms. The SLE and infection phenotypes can be separate or occur together in an individual.

**81.8.2.3 C2 Deficiency.** C2 deficiency is the most common of the inherited complement component deficiencies in Caucasians with a frequency of 1:10,000. The common Caucasian mutation is a 28bp deletion. Most C2 deficient individuals are asymptomatic although their susceptibility to infection is thought to be increased. Twenty to forty percent of C2-deficient individuals will develop SLE (49–51). Anti-Ro antibodies are common in C2-deficient patients with SLE although anti-dsDNA antibodies are infrequent (52). In spite of SLE being the most common phenotype, the most common cause of death among C2 deficient patients is sepsis (49). Other systemic infections such as meningitis, pneumonia, epiglottitis and peritonitis have been seen and the most common organisms have been *Streptococcus pneumoniae* and *Haemophilus influenzae*.

**81.8.2.4 C3 Deficiency.** C3 deficiency is the least common of the complement cascade protein deficiencies and it has the most severe phenotype by far (53–57). All patients have a profound predisposition to infection and the infections are sometimes characteristic of neutrophil dysfunction (abscesses), humoral deficiencies (sinopulmonary disease) and complement deficiencies (sepsis, meningitis). Membranoproliferative glomerulonephritis occurs in one-third of the cases of C3 deficiency (50,51). One other feature of C3 deficiency deserves mention. During infections, a vasculitic rash may appear and symptoms of serum sickness may occasionally be seen. These unusual findings are due to the lack of immune complex solubilization by C3. C3 deficiency is rare, with fewer than 30 cases reported in the literature. There is a founder effect among the Afrikaans-speaking population (56). Hypomorphic C3 mutations have been identified in some patients with autoimmune disease but the phenotype and prevalence are not clear (58,59).

Activating mutations of C3 can be associated with aHUS. These patients have been infrequent but have all had mutations that inactivated the interaction of C3 with MCP, a loss that leads to chronic activation and consumption of C3. These patients have had diminished serum C3.

**81.8.2.5 MBL Deficiency.** MBL deficiency is common with 2–7% of people affected (60). There are common structural mutations that destabilize the higher order complexes (61) and several promoter mutations that lead to impaired production (61). Combinations of mild mutations can lead to complete loss of function. The consequences of MBL deficiency are controversial with data supporting an increased susceptibility to infection and other studies finding no effect (61–64). MBL deficiency may be a mild risk factor for infection but is unlikely to have a significant effect. Similarly, an effect on susceptibility to autoimmune disease has been proposed; however, the effect has not been consistently identified and if there is an effect, it must be small.

**81.8.2.6 MASP2 Deficiency.** MASP2 protein deficiency is seen in 5–10% of the population (65). The common polymorphism, D105G, leads to compromised interactions with MBL and ficolin. Additional polymorphisms have been identified in various populations but their functional effect has not yet been defined. Like MBL deficiency, it may represent a risk for infection but the effect is modest (64). There is no strong evidence for an association of MASP2 deficiency and autoimmune disease.

**81.8.2.7 Factor B Deficiency.** A single case of complete factor B deficiency in a patient with meningococcemia has been reported (66). The disorder was suspected after studies demonstrated a low C3 and an absent AH50. No mutation was characterized; however, abnormal protein was seen on electrophoresis. Heterozygous gain-of-function mutations of factor B are found in approximately 2–4% of patients with aHUS.

**81.8.2.8 Factor D Deficiency.** Neisserial infections are the most common manifestation of factor D deficiency (50,51,67). Factor D deficiency should be suspected when the AH50 activity is absent.

**81.8.2.9 Properdin Deficiency.** Properdin deficiency is the only X-linked complement deficiency and the identified mutations have been diverse, with some affecting protein function and some having a null phenotype. Approximately half of the properdin deficient individuals present with meningococcal disease (50,51,68–71). There is a high fatality rate in meningococcal disease in properdin deficient patients. There may be a founder effect in Tunisian–Jewish people; however, properdin deficiency is seen on all ethnic backgrounds.

### 81.8.3 Defects in Proteins in the Membrane Attack Complex

**81.8.3.1 C5 Deficiency.** C5 deficiency is associated with susceptibility to meningococcal and gonococcal disease.

C5 deficiency is found on a variety of ethnic and racial backgrounds and the mutations are diverse.

**81.8.3.2 C6 Deficiency.** C6 deficiency is one of the most common complement disorders and occurs more frequently in African Americans and in people of South Africa. C6 deficiency is associated with meningococemia, meningococcal meningitis and disseminated gonococcal disease (50,51,72,73). There are two notable mutations associated with variants of C6 deficiency. In one case, a splice defect leads to a smaller than usual protein, C6SD (74). This protein functions less efficiently than wild-type C6; however, it is not clear whether bearing C6SD leads to compromised host defense. The other variation is combined C6 and C7 deficiency (75).

**81.8.3.3 C7 Deficiency.** C7 deficiency is not particularly common and the most common presentation has been neisserial disease (50,51,76). There may be a founder affect among Moroccan Jewish kindreds (77) but generally the mutations are diverse (76).

**81.8.3.4 C8 Deficiency.** C8 is composed of three chains:  $\alpha$ ,  $\beta$ ,  $\gamma$ . The  $\alpha$  and  $\gamma$  chains are covalently attached and bind to the  $\beta$  chain. C8 $\beta$  deficiency is more common in Caucasians whereas C8 $\alpha$ - $\gamma$  deficiency is more common among African Americans and Japanese (78–81). The majority of the C8 $\beta$  mutations are due to a single base-pair transition leading to a premature stop codon (80,82). The majority of the C8 $\alpha$ - $\gamma$  mutations are due to a 10-bp insertion leading to a stop codon (78). All types of C8 deficiency are associated with susceptibility to neisserial disease (50,51). Meningococcal meningitis, meningococemia and disseminated gonococcus have been seen.

**81.8.3.5 C9 Deficiency.** C9 deficiency is seen with high frequency in Japan and Korea (83–85). Approximately 0.05% of the population in Japan is C9 deficient. It is more difficult to diagnose than most of the other complement cascade protein deficiencies because the CH50 is diminished but not absent (86). As is true for the other terminal complement component deficiencies, C9 deficiency is associated with neisserial disease although the penetrance appears to be less than that seen in other terminal component deficiencies (87). The common Japanese mutation is a nonsense mutation in exon 4 (88).

## 81.8.4 Defects in Regulatory Proteins

**81.8.4.1 C1-Inhibitor Deficiency.** C1-inhibitor deficiency is associated with recurrent episodes of submucosal or subcutaneous edema (89). It is unusual in that it is most classically due to a heterozygous mutation and is inherited in an autosomal dominant fashion, although homozygous deficient patients exist (23,90–93). Serum levels are typically slightly less than 50% of normal due to accelerated consumption and in those cases where serum protein levels are normal, the functional level is slightly less than 50% of normal. Approximately half of the patients present in childhood. Rare asymptomatic

subjects have been identified. The frequency of angioedema episodes is highly variable, as is the severity. The extremities, face, genitalia and gastrointestinal tract are most often involved. Appendectomy and exploratory laparotomy for abdominal pain due to intestinal swelling are frequently performed (89). Upper airway swelling can lead to respiratory arrest. This complication can occur in as many as 2/3 of patients with C1-inhibitor deficiency, although improved management has made it less common. Prior to modern management, slightly over 10% of patients underwent a tracheostomy as a result of airway episodes.

The angioedema typically progresses for 1 to 2 days and resolves in another 2 to 3 days. Many people cannot identify precipitants, but common triggers are illness, hormonal fluctuations, trauma and stress. The C1-inhibitor promoter is androgen responsive, which is why men can be less severely affected than female patients (94–96). It is also the mechanism underlying the oldest therapeutic modality, attenuated androgens.

**81.8.4.2 C4 Binding Protein Deficiency.** A single kindred with C4 binding protein deficiency has been described (97). Angioedema, vasculitis and arthritis were seen.

**81.8.4.3 Factor I Deficiency.** Factor I deficiency has two phenotypes and the genotype–phenotype relationship is not fully understood. When factor I is lacking, C3 cleavage occurs unchecked and a secondary deficit in C3 occurs. Both the CH50 and AH50 are depressed but not absent and C3 antigen levels are low (98–101). Neisserial disease and infections with *S. pneumoniae* and *H. influenzae* have been described (50,51). The infection phenotype is most often associated with autosomal recessive mutations.

The second phenotype is renal disease, either aHUS or membranoproliferative glomerulonephritis II (102–104). These cases of factor I deficiency are difficult to identify because traditional complement studies are often normal. The factor I level is typically normal as the mutations inactivate critical binding sites. The fenestrated endothelium of the glomerulus is rich in polyanions, where complement can be activated in the absence of regulatory proteins. Mutations most often affect the catalytic domain (105).

**81.8.4.4 Factor H Deficiency.** Infections, aHUS, and macular degeneration are the main phenotypes seen in factor H deficiency (106–109). There is a strong genotype–phenotype correlation and factor H mutations are often heterozygous mutations. The infections are due to consumption of C3 and a secondary partial C3 deficiency (110). C3 levels are typically diminished and the CH50 and AH50 are low. Factor H levels may be diminished. The mutations associated with this phenotype are diverse. The other two phenotypes are less likely to be associated with low factor H levels, and mutation testing is typically required. Kindreds with membranoproliferative glomerulonephritis have been

identified with factor H deficiency and an acquired phenocopy is due to autoantibodies directed to factor H (111). The most common phenotype is now known to be aHUS. Factor H defects were found to be the underlying basis for 15–30% of patients with a HUS (112). Mutations typically occur at the C-terminus. Both autosomal recessive and heterozygous mutations have been seen. The disease is typically early onset and severe with recurrences in many cases (113).

A common tyrosine–histidine polymorphism of factor H (the His402 variant) was identified as a risk factor for macular degeneration (106,114). The retinal deposits called drusen contain factor H and terminal complement components. This polymorphism affects protection of the endothelium allowing smoldering complement activation and gradual damage.

**81.8.4.5 Membrane Cofactor Protein (CD46) Deficiency.** MCP deficiency is associated with a later onset of aHUS compared with factor H and factor I deficiencies (113,115–117). MCP mutations are thought to account for approximately 10% of all aHUS (112). In contrast to factor H and factor I deficiencies, renal transplantation can be successful because MCP is expressed on the kidney; however, relapses have been described (118,119). Traditional complement analyses are normal.

**81.8.4.6 CD59 Deficiency and Paroxysmal Nocturnal Hemoglobinuria.** A single patient with CD59 deficiency has been described and the major manifestation was chronic hemolytic anemia and recurrent stroke (120). CD59 confers protection from intravascular complement-mediated lysis and is expressed on hematopoietic cells and endothelial cells.

Paroxysmal nocturnal hemoglobinuria is due to acquired somatic mutations of PIG-A or PIG-M (121). These proteins are required for GPI anchored proteins such as C8 binding protein, DAF and CD59 (122). The diagnosis of PNH is made by flow cytometry for CD59 or CD55 (DAF).

**81.8.4.7 DAF Deficiency (CD55).** DAF deficiency is also termed the Inab blood group phenotype (123–125). DAF deficiency has no clear phenotype. Although, red cells may be slightly more sensitive to lysis (126).

**81.8.4.8 CR3/CR4 Deficiency.** This disorder is a defect in the three  $\beta$ 2-integrin adhesion molecules. This deficiency is more often called leukocyte adhesion deficiency type I (LAD type I). Mutations in the common  $\beta$  chain (CD18) lead to failure to express adequate  $\alpha$  chains (127,128). This disorder will be discussed in more detail in the chapter on immunodeficiencies.

## 81.9 MANAGEMENT OF COMPLEMENT DEFICIENCIES

The management of complement deficiencies is dependent on the type of defect. With few exceptions, there are no trials supporting the management strategies offered

here. The management approaches offered in this chapter represent possible interventions based on current literature. As this is a rapidly moving field, it is wise to seek out expert advice when confronted with a complement deficient patient.

### 81.9.1 Early Classical Component Deficiencies

C1, C4 and C2 deficiencies are all associated with bacterial infections and SLE. The treatment for SLE in these patients does not differ from standard approaches, although the more severely affected patients could in theory be treated with a liver transplant.

To mitigate the susceptibility to infection, patients are often vaccinated to raise the titers of antibodies to encapsulated organisms. For early complement component deficiencies the major risks seem to be *S. pneumoniae* and *H. influenzae* (49–51). Vaccines to these entities exist and there is reason to believe that having high titers of antibody may offer protection. Alternatively, antibiotics may offer protection from serious infection. In one study, half of the C2-deficient patients had serious infections such as sepsis and infection was the leading cause of death, accounting for over 10% of the deaths in this cohort (49). One-quarter of the patients had meningitis. Patients on immunosuppressive medication for rheumatologic disorders may require yet more vigilance and protection.

### 81.9.2 C3 Deficiency

The infections seen in C3-deficient patients are the most severe of any of the complement deficiencies and management must address loss of opsonization, loss of B-cell costimulation and loss of immune-complex solubilization (110). Immune globulin replacement is sensible to compensate for the compromised B-cell function and prophylactic antibiotics could ameliorate the risk of infection. The membranoproliferative glomerulonephritis seen in C3-deficient patients has no specific intervention, although renal transplantation has been attempted. The recurrence risk has not been characterized; however, one would anticipate some recurrence risk. Those patients with aHUS are often treated as other patients with HUS acutely. Fresh frozen plasma (FFP) can be administered to replace C3. Liver transplantation has not been performed but could be considered given the severity of the disease.

### 81.9.3 Factor D and Properdin Deficiency

Patients with factor D and properdin deficiency are susceptible to neisserial disease as well as *S. pneumoniae* and *H. influenzae*. Vaccination to achieve high titers of antibody to those entities could theoretically provide benefit. Traditionally, prophylactic antibiotics have been

used for some patients in an effort to prevent infections (129–131).

#### 81.9.4 Defects Associated with a Risk of Neisserial Infections

Terminal component deficiencies are all associated with an increased risk of neisserial disease. Meningococcal disease is by far the most common, but disseminated gonococcal infections have been described. Vaccination every 3 years with the meningococcal vaccine decreases the frequency of meningococcal episodes but does not eliminate them (132–135). The frequency is decreased to 20% of what non-vaccinated individuals experienced. No study has examined prophylactic antibiotics and it may be that careful monitoring and hyper-vaccination may be sufficient. Factor H and factor I deficiencies can also be associated with susceptibility to neisserial infections. There are no data to support a specific treatment strategy but the interventions described for patients with terminal components deficiencies could be considered.

#### 81.9.5 C1-Inhibitor Deficiency

Current management is evolving rapidly due to the recent release of C1-inhibitor products and a kallikrein inhibitor. Management differs in other countries but in the United States current management options include attenuated androgens to raise expression of the intact gene, C1 inhibitor and ecallantide (a kallikrein inhibitor). Each have demonstrated efficacy. Each may be used to treat acute episodes but ecallantide has not been approved as a preventive strategy. Although attenuated androgens such as danazol and oxandrin can be used to treat acute episodes, their effect is slow compared with C1-inhibitor products or ecallantide. For high-risk surgical procedures, C1 inhibitor is preferred although FFP may be used if C1 inhibitor is not available.

#### 81.9.6 Defects Associated with aHUS

As is done for typical acute hemolytic uremic syndrome, some patients receive pheresis and FFP replacement (115,136,137). In the longer term, one study found that factor H replacement prevented episodes, suggesting that FFP alone might be of benefit as prophylaxis for those patients with defects in soluble proteins. In the case of MCP, where the affected protein is membrane bound, it is less clear that pheresis and FFP would provide benefit, but it could potentially act to clear inciting agents or complement activation products (138). For patients with end-stage renal disease, the recurrence of disease in patients with soluble factor deficiencies is unacceptably high and renal transplantation is not recommended (118,119). In contrast, renal disease in MCP typically does not recur in the transplanted kidney. A combined liver and kidney transplant has been performed successfully, although

the preparative regimen was complex (139). A monoclonal antibody directed at C5 (eculizumab) was recently shown to be of benefit on aHUS and may become a useful adjunct in the transplant setting (140).

### Biography

**Dr Sullivan** is the Chief of the Division of Allergy Immunology at The Children's Hospital of Philadelphia (CHOP) and Professor of Pediatrics. She is also the Allergy Immunology training program director and directs the outpatient Immunology clinic, which has a census of over 1000 patients. On a national level, she is a founding member of the USIDNET Registries Committee, and is a member of the USIDNET Steering Committee. The goal of USIDNET is to develop resources for immunologist and to establish a longitudinal database of immune deficient patients. She was the 2007–2008 president of the Clinical Immunology Society and is on the Medical Advisory Board of the Immune Deficiency Foundation. She also serves as a consulting immunologist for the Immune Deficiency Foundation. In addition, she is a regular contributor to the two major textbooks of Pediatric Immunology and a major textbook of Metabolic Disorders.

This article is a revision of the previous edition article by Kuender D Yang and Harry R Hill, volume 2, pp 1868–1889, © 2007, Elsevier Ltd.

### 82.1 INTRODUCTION

Over the years 1950–2010, the field of phagocytic disorders has attained major biologic and clinical significance and a great deal of literature has accumulated on these disorders, which are frequently hereditary. Recently, owing to the development of exciting new advances in molecular biology and cellular physiology of signal transduction, it has been possible to identify the genetic defects involved in many of these phagocyte disorders. Moreover, through immunopharmacologic intervention, bone marrow transplantation (BMT), and the prospect of gene therapy, we have begun to at least partially correct genetic defects in cell activation pathways in phagocytes. Prenatal diagnosis employing first restriction fragment length polymorphism (RFLP), polymerase chain reaction (PCR) techniques and, more recently, scanning by high-resolution melting analysis and direct DNA sequencing, along with the assessment of granulocyte function in fetal blood have made these diseases potentially preventable, treatable in utero, or shortly after birth.

### 82.2 HISTORICAL BACKGROUND

In the late 1800s, Metchnikoff first established that the essential and primary element in typical inflammation consists of a reaction of the phagocyte against a harmful agent (1). Earlier, it was believed that phagocytes were harmful to the host and that they contributed to the untoward consequences of bacterial infection. After establishing that phagocytes were helpful in defense against bacteria, Metchnikoff predicted that defects in phagocyte function might predispose the host to an increase in the numbers and toxicity of infection with microorganisms. The past 60 years of clinical and laboratory definition of phagocyte disorders have proved this

hypothesis as patients with phagocyte function defects, with either quantitative or qualitative disorders, tend to have recurrent severe or even fatal bacterial and fungal infections.

Kostmann (2) identified an autosomal-recessive quantitative phagocyte disorder resulting in severe congenital granulocytopenia ( $<1500/\text{mm}^3$ ). Patients with Kostmann disease (also called infantile genetic agranulocytosis or severe congenital neutropenia (SCN)) usually have severe, chronic, and eventually fatal bacterial infections starting early in life. Evidence suggests that some cases are transmitted as an autosomal-dominant trait, whereas others are sporadic or rarely X-linked. There are now at least 15 gene defects known to cause SCN, but in about 30% of cases, the genetic etiology is still unknown.

Quie et al. (3) provided the first evidence of an inborn error of phagocyte bactericidal activity in a disease, then termed fatal chronic granulomatous disease (CGD). The authors found that granulocytes obtained from patients with CGD were able to ingest bacteria normally, but were unable to kill the internalized organisms. This disease, which often resulted in fatal granulomatous infection of childhood (4), most frequently occurred in boys, suggesting an X-linked mode of inheritance (5). Of additional interest was the observation that granulocytes from the mothers (presumed carriers of an X-linked disorder) were intermediate in their bactericidal capacity. Not only did these observations establish the first intrinsic defect of phagocyte function, but also the intermediate bactericidal defect in maternal granulocytes was consistent with the Lyon hypothesis. Baehner and Nathan (6) demonstrated a primary metabolic abnormality in granulocytes from CGD patients using a yellow dye, nitroblue tetrazolium, which turns to blue formazan in the reduced state

when superoxide is generated. Normal granulocytes stimulated to ingest and kill bacteria reduced the dye, whereas similarly stimulated granulocytes obtained from patients with CGD were unable to reduce the dye into blue formazan. Again, maternal granulocytes were found to be intermediate in dye reduction capacity. Hohn and Lehrer (7) reported that CGD granulocytes had defective NADPH oxidase activity. Segal et al. (8) showed that membrane cytochrome  $b_{245}$  (also called  $b_{558}$ ), a component of the NADPH oxidase, was missing in X-linked CGD granulocytes. Evidence existed, however, that some of the patients with CGD had an autosomal-recessive trait with intact membrane cytochrome  $b_{558}$  on granulocytes (9). The defective genes resulting in autosomal-recessive CGD have now been identified. The X-linked CGD gene coding for the cytochrome  $b_{558}$  heavy chain (p91phox), a component of the NADPH oxidase complex, is located on the short arm of the X chromosome; the autosomal-recessive genes encoding other components of the NADPH oxidase complex, including cytosolic factors p67phox and p47phox and cytochrome  $b_{558}$  light chain (p22phox), are located in chromosomes 1, 7, and 16, respectively (10). A small G protein, p21 Rac, is also involved in the activation of NADPH oxidase (11). Defects in any component of the NADPH oxidase complex can impair phagocyte oxidative bactericidal activity, resulting in CGD. These results suggested that a biochemical event under genetic control was the underlying basis for the bactericidal defect. In addition, the fact that phagocyte bactericidal activity can be individually controlled by a specific gene distinct from other phagocyte functions, such as adhesion, movement, and ingestion, suggests that these other phagocyte activities might also be individually controlled by specific genes.

From 1950 to 2010, these hypotheses have been proved true. An entire spectrum of phagocyte disorders, including adhesion, movement, ingestion, and bactericidal defects, has been recognized and their genetic bases are determined. Serious phagocyte function defects such as seen in leukocyte adhesion disorder (LAD) and CGD may occur as frequently as 1 in 250,000 people. Other minor phagocyte defects, such as myeloperoxidase (MPO) deficiency, have an even higher incidence of approximately 1 in 4000 to 1 in 2000. These minor disorders, however, do not often result in severe infections; for example, MPO deficiency is often asymptomatic, but can cause abnormal laboratory testing. This chapter highlights the current status in this exciting field and points out the possibilities for prenatal diagnosis, immunopharmacologic correction, and gene therapy based on the genetic defects, as well as the biochemical and physiologic aberrations of phagocytes. To understand the individual phagocyte defects, a comprehensive understanding of normal phagocyte development, kinetics, and function is essential.

## 82.3 PHAGOCYTE DEVELOPMENT, KINETICS, AND FUNCTIONS

### 82.3.1 Development

There is evidence that human myelopoiesis occurs early in fetal life—as early as 6–8 weeks of gestational age (12,13). Phagocyte progenitor cells arise from pluripotential hematopoietic stem cells in the bone marrow. These precursors can give rise to mature phagocytes, including polymorphonuclear granulocytes and mononuclear phagocytes, under the influence of various colony-stimulating factors: stem cell factor, granulocyte–macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), and interleukin (IL)-3. These growth and differentiation factors are derived mostly from the stromal cells in the bone marrow, but some are produced by myeloid cells in the reticuloendothelial system (14). The development of granulocytes from hematopoietic stem cells to common myeloid progenitors, then to granulocyte–monocyte progenitors, and finally to mature granulocytes and monocytes is controlled by transcriptional factors (15). The differentiation of myeloid progenitors into mature phagocytes probably results in part from the acquisition of specific factor receptors on the cells at different phases of differentiation and maturation (reviewed by Yang and Hill (16,17)). Interaction of lectins in the stromal cells with receptors on phagocyte precursors may also be involved in the process of growth and differentiation (14). Phagocytes obtained from a 20-week gestational age fetus reveal active phagocytic and respiratory burst activity. Phagocytes in a full-term newborn, however, do not have complete functional activity. Neonatal granulocytes and monocytes have defects in bone marrow storage pools, cellular activation, and chemotaxis (18–22). Studies with adult phagocytes have indicated that a variety of cytokines and glycoproteins can modulate phagocyte function. These results suggest that intact phagocyte function is due to intrinsic maturation, but is also modulated by environmental factors that alter the granulocyte's biochemical and physiologic status. It is necessary to differentiate intrinsic defects from extrinsic environmental abnormalities.

### 82.3.2 Kinetics of Granulocytes

Granulocytes are produced in the bone marrow and released into the blood and tissues, where they act as the first line of defense in host resistance and wound healing (13). The total granulocyte pool is divided into two compartments: the bone marrow and the circulating pools. The bone marrow provides the environment for the proliferation of myeloblasts, promyelocytes, and myelocytes, as well as the maturation of metamyelocytes and band-form granulocytes. The latter two populations represent the main marrow storage pool of granulocyte precursors, containing  $6-8 \times 10^9$  cells/kg. The recycling

and the proliferation and maturation phases of granulocytes in bone marrow require 2–3 days and 7–10 days, respectively (16,17,23). In the blood, granulocytes are in the circulating pool ( $0.3\text{--}0.4 \times 10^9$  cells/kg) and marginating pool ( $0.4 \times 10^9$  cells/kg). Endotoxin, corticosteroids, and complement fragments (C3e, C3d,g) cause accelerated release of mature granulocytes into the circulation. Adrenergic neurotransmitters such as epinephrine and norepinephrine can promote granulocyte mobilization from the marginating pool into the circulatory pool. Granulocytes in the circulation have a short circulating transit time of about 6–9 h. Certain patients with LAD have a longer circulating time (24). In contrast, patients after multiple blood transfusion may have a shorter circulating time of <1 h (25). In spite of this short half-life, granulocyte numbers in the blood are normally maintained between 3000 and 6000 cells/mm<sup>3</sup>.

### 82.3.3 Kinetics of Monocytes/Macrophages

Monoblasts are the first recognizable cells in the monocyte series in the bone marrow (26,27). However, few monoblasts are found in the bone marrow as the storage pool of these cells is relatively small. The transit time from monoblast to monocyte takes about 6 days (28). Promonocytes are the prominent cells of the monocyte series in the bone marrow, with a major storage pool containing  $6 \times 10^8$  cells/kg (29). Promonocytes mature into monocytes in the bone marrow and are released into the blood within 2 days. Circulating monocytes in the blood make up 3–8% of the total leukocytes ( $300\text{--}600$  cells/mm<sup>3</sup>, or  $0.3 \times 10^8$  cells/kg), and three to four times more monocytes marginate in the blood. These monocytes leave the circulation with a transit time of 1–3 days (23,28,29). Every day, approximately 108 monocytes are released into the bloodstream and leave for the tissues. These monocytes become transformed into a variety of tissue macrophages, depending on conditions in different tissues (26,27). They then remain in tissues as macrophages for months or even years. The monocyte–macrophage system is also widely distributed in a number of organs as microglial cells in the brain, Kupffer cells in the liver, osteoclasts in the bone marrow, Langerhans cells in the skin, mesangial cells in the kidney, and resident macrophages in the lungs, spleen, thymus, lymph nodes, pleuroperitoneal cavity, and joint spaces. Immature monocytes can also develop into dendritic cells that distribute to all tissues and act as professional antigen-presenting cells (30). During acute inflammation, the transit time of monocytes from the bone marrow to the inflammatory tissue may be shortened from 2 days to 6–8 h. In contrast to granulocytes, which do not replicate in the circulation or in tissues, both circulating monocytes and tissue macrophages are able to replicate rapidly. In chronic inflammation, tissue macrophages may transform into

giant cells or epithelioid cells in the presence of tumor necrosis factor (TNF)- $\alpha$  and interferon- $\gamma$  (IFN- $\gamma$ ) (28,29), especially in a variety of granulomatous disorders. Defects in IFN- $\gamma$  receptor result in the absence of granuloma formation in normally avirulent mycobacterial infections (31).

### 82.3.4 Functions of Granulocytes

Granulocytes can become activated in the blood circulation and in interstitial tissues. Activation of granulocytes requires several integrated signal pathways. A small G protein, Rac2, is specifically involved in triggering respiratory burst activity (11,32). A GTPase, Cdc42, together with Wiskott–Aldrich syndrome protein (WASp) activates actin assembly (33). Another small G protein, Ras, regulates phosphatidylinositol-3-kinase activities for coordination of granulocyte migration (34). Moreover, different G proteins can be coupled to different receptors and mediate the degranulation of granulocytes (32). The differentiation and activation of granulocytes are also regulated by mitogen-activated protein kinases such as p38 and MEK signaling (35,36). Adhesive glycoproteins on granulocytes, including selectins such as L-selectin, as well as integrins such as the complement receptors CR3 and CR4, promote granulocyte adhesion (37,38). Selectins are involved in granulocyte rolling in the blood circulation, whereas integrins mediate granulocyte extravasation (37,38). In response to chemoattractants, C5a, IL-8, platelet-activating factor, leukotrienes, and bacterial formylated peptides (fMLP), granulocytes reorganize their cytoskeleton and migrate into tissues and inflammatory sites, where they interact with and ingest target organisms, especially if the microbes are coated with immunoglobulin or complement. This interaction of granulocytes with microbes is followed by ingestion, respiratory burst activity, and degranulation. Reactive oxygen intermediates released from the respiratory burst, and lysosomal enzymes and cationic proteins released from degranulation of primary and secondary granules, respectively, contribute to oxygen-dependent and oxygen-independent bactericidal activities, resulting in extracellular and intracellular killing of microorganisms. Moreover, oxygen radicals are involved in nuclear factor- $\kappa$ B (NF- $\kappa$ B) activation for defense against bacterial infection (39).

There is also evidence that granulocytes have an important role in inflammatory and degenerative reactions arising during tissue injury, tumor invasion, viral infection, autoimmune disorders, aging, and atherosclerosis. Enhancement of granulocyte adhesiveness to endothelium may result from thermal injury, hypoxia, bacterial sepsis, and immune complexes. On traumatic injury, platelets adhere and aggregate on the vascular endothelium and subsequently release chemotactic factors such as leukotriene B<sub>4</sub>, transforming growth factor- $\beta$  (TGF- $\beta$ ), and platelet-derived growth factors. This

results in a rapid recruitment of granulocytes and fibroblasts that have a central role in tissue inflammation and wound healing (16). Thermal injury, hypoxia, and bacterial sepsis may cause adult respiratory distress syndrome, probably as a result of enhanced and sustained granulocyte adhesiveness followed by release of toxic granulocyte-derived mediators (16,40). Immune complexes, either alone or accompanied by complement activation, may also promote granulocyte influx, adhesiveness, respiratory burst activity, and degranulation, contributing to vasculitis and autoimmune inflammatory reactions. Hyperreactive oxygen metabolites produced by the respiratory burst are able to damage DNA and cause endothelial damage, resulting in aging and atherosclerosis. Cationic proteins released during degranulation of granulocytes are also involved in the cytotoxicity. Interferon-like substances released by granulocytes have been implicated in the inhibition of virus replication. Furthermore, granulocytes have been shown to mediate antibody-dependent cellular cytotoxicity (ADCC) against tumors and viruses, especially in the presence of cytokines such as interferon and GM-CSF. Defects or abnormal activation in any aspect of these granulocyte responses may result in immunodeficiency diseases or serious inflammatory disorders. For patients with life-threatening granulocyte function deficiency, transfusion of granulocytes may be required. In contrast, patients with inflammatory disorders, such as ulcerative colitis, may require granulocyte/monocyte apheresis (41).

### 82.3.5 Functions of Monocytes/Macrophages

Monocytes may develop into different forms of dendritic cells and macrophages, possessing diverse morphologies and functions depending on environmental and immunologic factors. Mononuclear phagocytes, similar to polymorphonuclear granulocytes, can move toward foreign invaders and denatured tissues and destroy them by ingestion, degranulation, and respiratory burst activity. On maturation into macrophages, cells of the monocyte series show an increase in size, adhesiveness, and functional receptors (e.g. CR1, CR3 FcRI and FcRII), resulting in enhancement of phagocytosis (29,42). Studies have shown that cells of the monocyte series have relatively low microbicidal activity compared to granulocytes. Tissue macrophages usually lose their MPO, which mediates a potent microbicidal activity by catalyzing halides into hypohalites. Loss of MPO may be a developmental milestone resulting in harmless contact between cells of the monocyte series and other immune cells required for antigen presentation. Increases in lectin-like receptors, as well as receptors for lipoproteins, are found mainly on macrophages but not on monocytes. Defects in the former may impair nonimmunologic reticuloendothelial clearance, whereas dysregulation of lipoprotein uptake by macrophages may give rise to atherosclerosis.

Apart from the professional function of “phagocytosis,” cells of the monocyte series have a central role in antigen presentation as well as modulation of inflammation and tissue repair. Dendritic cells that derived from monocytes or other lineage cells are particularly effective in antigen presentation to T cells (43,44). They are termed professional antigen-presenting cells (30). Monocytes and their derived dendritic cells bearing Toll-like receptors (TLRs) are responsible for bacterial and viral recognition and signal transduction, as these cells serve as a link between innate and adaptive lymphocyte differentiation and activation (45–47). Monocytes recruited into the inflammatory area are able to release monokines, including IL-1 $\beta$ , IL-6, IL-8, IL-10, IL-12, IFN- $\alpha/\beta$  and TNF- $\alpha$ , to enhance lymphocyte infiltration and to present antigens to lymphocytes, resulting in lymphocyte transformation (46,48–51). On activation, monocytes ingest particles, produce reactive oxygen molecules, and release procoagulant factors and cytokines, as well as increase the expression of adhesive molecules and class II human leukocyte antigens (HLA). Procoagulant factors are involved in coagulation and homeostasis. Granules of the monocyte series contain lysozyme, proteases, elastase, and collagenase, which augment tissue damage. In contrast, granules containing  $\alpha_1$ -protease inhibitor,  $\alpha_2$ -macroglobulin, and IL-1 inhibitors may offer a mechanism to protect against tissue damage. Cytokines from cells of the monocyte series act in an endocrine (affecting distant cells by blood transportation), a paracrine (affecting adjacent cells), and an autocrine (affecting themselves) manner (23). For instance, IL-1 has an endocrine effect on the regulation of body temperature and sleep pattern in the hypothalamus. Paracrine cytokines from the monocyte series include GM-CSF, G-CSF, monocyte colony-stimulating factor (M-CSF), erythropoietin, TNF- $\alpha$ macroglobulin, and IL-1 inhibitors may offer a mechanism to protect against tissue damage. Cytokines from cells of the monocyte series act in an endocrine (affecting distant cells by blood transportation), a paracrine (affecting adjacent cells) and an autocrine (affecting themselves) manner (23). For instance, IL-1 has an endocrine effect on the regulation of body temperature and sleep pattern in the hypothalamus. Paracrine cytokines from the monocyte series include GM-CSF, G-CSF, M-CSF, erythropoietin, TNF- $\alpha$ , and TGF- $\beta$ , which are all known to be involved in immune regulation. Some of the cytokines also have an autocrine effect on the monocyte series themselves. For example, ligation of M-CSF to its receptor (a c-fms proto-oncogene product) on monocytes induces monocyte differentiation, activation, and proliferation. Furthermore, cells of the monocyte series are the only cell population in the phagocyte series that express both major histocompatibility complex (MHC) class I and MHC class II antigens. Antigens are taken up by the monocyte/macrophage series and processed via biochemical and physical reactions. These antigens are presented in a peptide form associated with MHC molecules, which

lymphocytes recognize as antigen–MHC molecular complexes. Cells of the monocyte series bearing the antigen–MHC class I complex can be recognized and killed by cytotoxic T cells, whereas those bearing antigen–MHC class II molecules interact with helper T cells, resulting in clonal expansion of antigen-specific lymphocytes. Cytokines such as IL-2, IL-4, IL-5, IL-13, or IFN- $\gamma$  from lymphocytes act in a paracrine manner to amplify monocyte functions. Eicosanoids such as prostaglandin E<sub>2</sub>, cytokines (e.g. TNF- $\alpha$ , TGF- $\beta$ ), and  $\alpha_2$ -macroglobulin from the monocyte series have an immunosuppressive effect. Dysregulation of the antigen-presenting process may cause immunodeficiency and autoimmune diseases.

## 82.4 GRANULOCYTE FUNCTION DISORDERS

### 82.4.1 Congenital Granulocytopenia (Growth and Differentiation Defects)

Granulocytopenia may result from a decrease in bone marrow production or an increase in peripheral destruction of cells by autoantibodies or the reticuloendothelial system. Congenital granulocytopenias are due to a decrease in bone marrow production resulting from defects in the growth and differentiation of granulocytes. Empirically, a blood granulocyte level  $<1500/\text{mm}^3$  is defined as granulocytopenia, and  $500/\text{mm}^3$  is usually considered severe granulocytopenia. It should be noted, however, that a baseline blood granulocyte level  $<1500/\text{mm}^3$  is not applicable to all populations. Approximately 25–50% of African descent and some ethnic groups in the Middle East have neutropenia not associated with an increased risk of infection called *benign ethnic neutropenia*. The white blood cell (WBC) count response to intense exercise, which reflects neutrophil demargination in response to catecholamine release, has also been found to be lower in people of African descent than in those of European descent (52). Importance of the different baseline value lies in the fact that it can lead increased blood testing, treatment interruptions and discontinuation. A single nucleotide polymorphism (SNP) that is associated with race is DARC rs2814778. DARC encodes the Duffy antigen receptor for chemokines and the common African variant confers protection from *Plasmodium vivax* infection and has a low WBC count (53). This variant explained approximately 20% of population variation in WBC.

### 82.4.2 Granulocytopenia

**82.4.2.1 Clinical Features.** Patients with congenital granulocytopenia usually have recurrent infections such as omphalitis, septicemia, and abscess formation early in life. Those who survive infancy frequently show progressive periodontitis.

**82.4.2.2 Genetics and Pathogenesis.** Several congenital (primary) granulocytopenias have been described, including SCN, cyclic neutropenia, and other syndromic

neutropenias (Table 82-1). Genetic agranulocytosis (Kostmann syndrome) was first identified as an autosomal-recessive disorder by Kostmann (2), but it took 57 years to find the genetic defect in the families described by Kostman (54). Reticular dysgenesis is due to failure of bone marrow production of blood stem cells, resulting in pancytopenia (55,56). The Shwachman syndrome is characterized by pancreatic insufficiency, granulocytopenia, and failure to thrive (57). Cyclic granulocytopenia occurs in cycles, with periods of normal granulocyte counts of approximately 3 weeks, followed by granulocytopenia secondary to failure of maturation lasting approximately 1 week (58). It is now known that a variety of genes that can regulate granulocyte growth and differentiation at different levels can also affect the production of mature granulocytes.

**82.4.2.3 Diagnosis and Differential Diagnosis.** The diagnosis of congenital granulocytopenia is based on a history of recurrent infections early in life associated with persistent granulocytopenia of  $<1500/\text{mm}^3$ . Some patients with congenital granulocytopenia may, however, have a benign or cyclic course and remain asymptomatic until childhood. For instance, patients with cyclic granulocytopenia have a variable course, from spontaneous recovery to recurrent infections associated with periodontitis. Shwachman syndrome is often confused with cystic fibrosis because of malabsorption and recurrent infections. In addition, nutrition, infections, drugs, irradiation, malignancy, hypersplenism, and even metabolic disorders may also cause granulocytopenia, so that one needs to exclude the possibility of a secondary disorder before making a diagnosis of congenital granulocytopenia.

**82.4.2.4 Management.** Most patients with genetic granulocytopenia tend to present with severe or fatal infections early in life. Bone marrow or stem cell transplantation from HLA-matched donors or T-cell-depleted haploidentical donor marrow may be able to rescue these patients if the diagnosis is established as early as possible. For those who survive into infancy or childhood with chronic and recurrent infections, the administration of growth factors such as GM-CSF, G-CSF, and a chimeric protein conjugating IL-3 with GM-CSF may be of benefit (50,59,60). Some patients responded to the treatment with growth factors, but certain patients have not shown any effect. For nonresponders, BMT or human umbilical cord blood stem cell transplantation may be required. Transfusion of irradiated granulocytes may be lifesaving in patients with overwhelming infections. In addition, early intervention with antibacterial and antifungal prophylaxis may be important as patients with granulocytopenia are more susceptible to infection with extracellular organisms, including bacteria and fungi.

### 82.4.3 Leukocyte Adhesion Disorders

Leukocyte trafficking from the bloodstream to the injured tissues is a multistep process (61). First, the leukocytes

tether to the activated vascular endothelial cells expressing selectins. The leukocytes then roll on the vascular endothelium. This rolling is mediated by fucosylated ligands. The rolling slows down the leukocytes allowing tight binding to the endothelium and eventual emigration into the tissues.  $\beta 2$  integrins expressed on the leukocyte surface mediate the tight binding to the endothelium. Rolling adhesion also enables the adherent leukocytes to become activated by locally presented chemokines. Leukocyte activation leads to further integrin (e.g. LFA-1, CD11a/CD18 and Mac-1, CD11b/CD18) expression. Leukocyte integrins interact with immunoglobulin-like counterreceptors on endothelial cells (ICAM-1, ICAM-2) to strengthen the adhesion and promote the transmigration of cells from the circulation into the underlying tissues. Leukocyte adhesion deficiency disorders are characterized by the inability of leukocytes to emigrate from

the circulation to the sites of injury. LAD-I is caused by mutations in the gene encoding the common  $\beta$ -chain of the  $\beta 2$  integrin family (or CD18). LAD-II deficiency in fucosylation of, among other molecules, the adhesion molecules is required for leukocyte rolling. LAD-III is caused by the deficient cytokine activation of the adherent leukocytes leading to diminished integrin expression.

The first LAD was characterized as the deficiency in a family of surface glycoproteins called the CD11/CD18 complex (62). The CD11/CD18 family of glycoproteins share an identical  $\beta$  chain (CD18, 95 kDa) and separate  $\alpha$  chains: CD11a (180 kDa), CD11b (165 kDa), and CD11c (150 kDa). CD11a/CD18, also called leukocyte function antigen-1 (LFA-1), is present on all leukocytes and facilitates lymphocyte adhesion, natural killing, T-cell cytotoxicity, and helper activity. CD11b/CD18, also called Mac-1 or CR3 and found on granulocytes, monocytes,

and macrophages, is a receptor for iC3b and mediates phagocyte adhesion-related functions and ADCC. CD11c/CD18, also called CR4, is found on monocytes and granulocytes and mediates functions similar to those mediated by CR3. Granulocytes from patients with CD11/CD18 complex deficiency, called LAD-I, show poor adhesion-related functions, including adhesion to endothelial cells, chemotaxis, and ADCC, as well as iC3b-mediated phagocytosis, particle-induced respiratory burst activity, and degranulation (63). In contrast, LAD-II is characterized by defective expression of selectin leukocyte ligand, resulting in poor homotypic aggregation and migration (64,65). LAD-II granulocytes are activated normally with upregulation of integrin molecules, but not with certain fucosylated antigens, such as the sialyl Lewis X blood group (sLex) and cutaneous lymphocyte antigens, which are missing on leukocytes (66). Another LAD called LAD-III has been deciphered involving a signal defect in Rap1 activation that results in poor integrin expression (67).

**82.4.3.1 Clinical Features.** Patients with LAD-I frequently have delayed separation of the umbilical cord, perirectal abscesses, and recurrent staphylococcal and gram-negative bacterial infections. Patients surviving infancy often have progressive periodontitis and gingivitis. Lymphocyte function in LAD-I patients is also impaired as CD18 is actively involved in specific interactions between lymphocytes and antigen-presenting cells. The severity of the clinical course is variable. Severe LAD-I often leads to death in infancy, whereas patients with moderate LAD-I survive into adulthood. The severity of infections is related to the degree of CD18 deficiency: severe deficiency is caused by severely diminished (1% or less of normal expression) of CD18, and in moderate disease, the patients demonstrate residual (2.5–10%) CD18 expression (Fischer A et al. *Immunol Rev* 1988). Patients with LAD-II also have peripheral blood neutrophilia, recurrent infections, and periodontitis. They do not have delayed separation of the umbilical cord or impaired lymphocyte functions, and the infections are usually milder. They do, however, demonstrate mental retardation and craniofacial abnormalities, a leukocyte locomotion defect, and low leukocyte adhesion to endothelial cells, along with severe reduction in leukocyte rolling. Some blood group antigens dependent on fucosylation are decreased or absent; LAD-II patients have the very rare Bombay blood group phenotype (absence of the fucosylation-dependent H antigen) and are Lewis a and Lewis b-negative (66,68). Patients with LAD-III were first described as LAD-I variants who suffered from a bleeding tendency in addition to recurrent bacterial infections, resulting from an activation defect in all major integrin family members expressed on leukocytes and platelets (67). Leukocytes from LAD-III patients demonstrate severely diminished adhesion and normal rolling like in LAD-I, but also have platelet aggregation deficiency.

**82.4.3.2 Genetics.** LAD-I (OMIM 116920) is inherited in an autosomal-recessive manner. Crowley et al. (69)

first reported its recessive inheritance and association with a missing glycoprotein. Parents and heterozygous siblings of patients express about half-normal amounts of these adhesive glycoproteins on their phagocytes. The disorder is the result of a deficiency in the synthesis of the CD18 molecule, resulting in defects in CD11–CD18 coupling as well as translocation of the complex onto the cell surface (63). Data from molecular studies have demonstrated that the gene coding for the synthesis of CD18 (or Integrin  $\beta$ 2; ITGB2) is located on chromosome 21q22.3 (70). LAD-II (OMIM 266265; or Congenital Disorder of Glycosylation, Type IIc, CDG2C) is caused by mutations in the SLC35C1 gene encoding a Golgi ADP-fucose transporter (71). It is inherited in an autosomal-recessive manner, resulting in deficiency of the selectin-binding ligand, sLex antigen. LAD-III is caused by a homozygous mutation in the FERMT3 (or KINDLIN3) gene (72). In LAD-III, the function of integrins on both leukocytes and platelets is disrupted because of the “inside-out signaling” defects in cytokine activation-dependent alterations of surface integrins that enable high-avidity binding to ligands on endothelium and platelets (73).

**82.4.3.3 Diagnosis and Differential Diagnosis.** Granulocytes and monocytes obtained from patients with LAD-I do not adhere well on plastic or glass plates or umbilical cord endothelial cells. A definite diagnosis of the disorder is based on flow cytometric analysis of cell membrane glycoproteins, using specific monoclonal antibodies. The patient’s phagocytes have normal HLA and CR1 antigen expression, but low to very low levels (0–10%) of CD11/CD18 glycoproteins on the cell surface (63). Leukocytosis with a predominant granulocytosis in the range of 20,000–100,000/mm<sup>3</sup> is common. The granulocytosis is most likely due to invasion by microorganisms, which result in complement activation and the production of other hemopoietic stimulants. This leads to an increase in bone marrow production and the egress of granulocytes into the blood circulation, where they cannot adhere or marginate on the endothelial layer (16). The granulocytosis, with almost all mature granulocytes, should be differentiated from a leukemoid reaction, in which a shift to the left in granulocyte morphology is prominent. Phagocytes obtained from patients with LAD-I reveal not only abnormal adhesion but also abnormal chemotaxis and phagocytosis, as adhesion is a prerequisite step for movement and engulfment. Thus, patients with LAD-I have quite similar clinical symptoms and findings to those with chemotactic or phagocytic defects. In general, however, no granulocytes are seen within their infections, so that there is no pus.

Differential diagnosis between LAD-I and LAD-II can be made by flow cytometric analysis of CD18 expression and by the assay of granulocyte adhesion to activated endothelial cells. Granulocytes from patients with LAD-I do not express CD18 on the cell surface. Granulocytes from LAD-II patients have normal CD18 expression but abnormal adhesion to IL-1-activated endothelial cells

(65,66), and their red blood cells have the characteristic Bombay (hh) phenotype. Antibodies directed against sLe<sup>x</sup> (CD15), such as the 7C3 antibody, can be used for analysis of sLe<sup>x</sup> expression (66). Leukocytes with LAD-III have impaired Rap1 activation associated with defective expression of all major adhesion molecules, and a bleeding tendency in the presence of normal platelet numbers (67).

**82.4.3.4 Management.** Patients with LAD-I can be effectively treated by BMT, the success rate for which has increased to around 70% (74). The possibility of employing gene therapy in the treatment of this disorder is currently being explored (75). Patients with moderate LAD-I phenotype usually respond well to prophylactic antibiotic therapy. Patients with LAD-II tend to have less-severe recurrent infections. They have prominent periodontitis but do not suffer intractable infections when appropriate antibiotic treatment is employed. These patients also have mental retardation that might dominate the phenotype past childhood. BMT or gene therapy has not proved to be a suitable approach in LAD-II. Fucose supplementation, however, might work in patients with the mutations leading to decreased fucose affinity transporter (76). Similarly, only a few LAD-III patients have been reported. LAD-III patients need antibiotic prophylaxis as well as blood transfusion as it is associated with a severe bleeding tendency and repeated infections. BMT is the only curative therapy.

## 82.4.4 Disorders of Granulocyte Chemotaxis

Granulocyte chemotaxis involves an organized ligand-receptor signal coupling response. A defect existing at any level in the response can affect granulocyte locomotion and chemotaxis, so that extensive heterogeneity among these disorders exists.

**82.4.4.1 Clinical Features.** In general, these patients suffer from cutaneous abscesses, sinopulmonary infections, chronic candidiasis, and other tissue infections. Patients with phagocyte chemotactic deficiency can be classified into five different categories based on the level of the defect.

### 82.4.4.2 Genetics.

**82.4.4.2.1 Defects at the Ligand Level.** A major physiologic ligand inducing phagocyte chemotaxis in human beings is C5a, a fragment of complement activation. Patients with a familial deficiency of complement components—C1, C2, C4, properdin, factor B, C3, and C5—may be unable to produce adequate amount of C5a. These complement components are genetically controlled by an autosomal-recessive or -codominant inheritance, except for properdin deficiency, which is an X-linked disease. Leiner disease is characterized by seborrheic dermatitis, recurrent gram-negative bacterial infections, intractable diarrhea, and failure to thrive (77). Patients with this syndrome are reported to have normal C5 levels,

but have C5 dysfunction associated with a humoral chemotactic defect (78). Patients with Leiner disease show spontaneous remission after 2 months of age. This disease has been found in both twins and consecutive family members, so that a genetic disease has been proposed. The fact that this disease is limited to breast-fed babies may, however, suggest a multifactorial disorder.

In the autosomal-recessive Papillon-Lefevre syndrome, loss-of-function mutations in cathepsin C result in periodontal disease and palmoplantar keratosis. Loss of cathepsin C leads to the failure to activate neutrophil serine proteases that, in turn, prevent the proteolytic degradation and inactivation of MIP-1 $\alpha$ . The loss of proteolytic cleavage of the chemokine MIP-1 $\alpha$  results in the dysregulation of the local inflammatory response and tissue destruction (79–81).

### 82.4.4.2.2 Defects in Cell-Surface Receptors.

Defects in chemotaxis at the membrane receptor level include the previously mentioned deficiency of the adhesive molecules (CD11/CD18 complex deficiency). Granulocytes with adhesive-glycoprotein deficiency are unable to adhere to endothelium or interstitial tissue, so that they show poor chemotaxis both in vivo and in vitro. Delayed separation of the umbilical cord, followed by the onset of recurrent tissue infections in which pus cells are absent, is characteristic of these patients. Juvenile periodontitis usually occurs in adolescents who have impaired chemotaxis and localized periodontitis and extraoral infection (82,83). Limited evidence suggests that this syndrome is due to a defect in a 108-kDa surface glycoprotein and transmitted by an autosomal-codominant trait (82).

WHIM syndrome is an autosomal-dominant disorder of Warts, Hypogammaglobulinemia, Infections, and Myelokathexis (84). WHIM patients have numerous warts on hand, feet and trunk as well as genital and anal condyloma acuminata, and cervical and vulval premalignant dysplasia due to papilloma virus (HPV) infections. The marked hypogammaglobulinemia results in recurrent upper respiratory infections, such as sinusitis, tonsillitis, otitis media, pneumonia. Myelokathexis refers to the retention of white cells in the marrow causing neutropenia, the bone marrow is hypercellular but there is an associated neutropenia. WHIM syndrome is caused by heterozygous gain-of-function mutations in the gene encoding CXCR4 chemokine receptor (85). WHIM syndrome is the first example of a human disease caused by dysfunction of a chemokine receptor. The neutropenia of WHIM syndrome is unique in that it responds to acute infection, and G-CSF, GM-CSF, epinephrine, or glucocorticoids and the neutrophil counts may reach normal levels within hours, hence the infections are usually not life threatening.

**82.4.4.2.3 Defects in the Mechanics of Cell Movement.** Granulocyte chemotactic deficiency due to cytoskeleton organization defects is seen in actin dysfunction. Granulocyte actin dysfunction, an autosomal-recessive disorder, usually results in a chemotactic defect and a defect in ingestion, as both require cytoskeleton

reorganization and actin polymerization. Miller et al. (86) described a primary disorder of granulocyte movement with what appeared to be a hereditary basis. Three children in two families presented with a symptom complex of congenital ichthyosis and *Trichophyton rubrum* infections. Granulocytes obtained from the patients and their fathers showed abnormal directed movement but normal random motility. On further investigation, it was found that each father had been troubled with chronic cutaneous candidiasis throughout most of his life. These findings suggested a familial chemotaxis defect with autosomal-codominant traits.

**82.4.4.2.4 Defects Associated with Impaired Degranulation.** Granulocytes with specific granule deficiency, an autosomal-recessive disease, have a chemotactic receptor recycling defect resulting in a chemotactic defect (87). Granulocytes from patients with Chédiak–Higashi syndrome (CHS) have a chemotactic defect based on altered microtubule function and membrane regulation in which elevated cyclic AMP (cAMP) is prominent (88). Evidence showed that the CHS protein is widely distributed in the cytosol but not the membranes (89), suggesting that the CHS protein may act to regulate lysosomal fusion and membrane regeneration. This disease is transmitted as an autosomal-recessive trait, and is caused by homozygous or compound heterozygous mutation in the lysosomal trafficking regulator gene (LYST on chromosome 1q42.1–1q42.2 (90–93)). There are also some other syndromes similar to CHS demonstrating hypopigmentation and leukocyte function deficiency. Patients with Griscelli syndrome (GS) have a defect in myosin V, a molecule involved in organelle transportation (94). These patients also demonstrate partial albinism and cellular deficiency. The gene encoding the myosin V protein is located on chromosome 15q21 (94,95). Some forms of oculocutaneous albinism, may also have neutropenia (96): Type 2 Hermansky–Pudlak syndrome (HPS) is an autosomal-recessive disorder characterized by oculocutaneous albinism, bleeding disorders, recurrent infections, and neutropenia. The disease is caused by mutations in the AP3B1 gene encoding for the beta3A subunit of the adapter protein 3 (AP-3) complex. Because the expression of the beta3A subunit is normally ubiquitous, its deficiency leads to a phenotype in all cells with intracellular granules, such as neutrophils, natural killer cells, cytotoxic T lymphocytes, platelets, and melanocytes (97).

**82.4.4.2.5 Extrinsic Suppressive Factors.** Many extrinsic suppressive factors, such as immune complexes (98), steroids, and immunoglobulin (Ig)A paraproteins (99), can interfere with phagocyte chemotaxis. A common and life-threatening condition, sepsis, can lead to the suppression of neutrophil migration, and this “neutrophil paralysis” is directly related to the severity of the disease (100,101). The hyper-IgE syndrome (HIES or Job syndrome) (102) is usually associated with a granulocyte chemotactic defect (103) and high levels of IgE, altered T-cell activity (104), and low IFN- $\gamma$  and IL17 production

(105,106) The granulocyte chemotactic defect appears to have both intrinsic and extrinsic components although these have not been identified yet (107). HIES is inherited as an autosomal-dominant trait in certain families although most of the cases are sporadic (108–111). HIES is caused by mutations in STAT3 (112–116). Mutations in HIES are always heterozygous missense mutations or in-frame deletions; no homozygous mutations or nonsense mutations are seen. Homozygous Stat3-deletion is incompatible with life in mouse experiments, whereas the heterozygous littermates have no phenotype (117), suggesting that the cause of HIES is not haploinsufficiency, but a dominant-negative effect. The likely explanation of the dominant phenotype is that the STAT proteins work as dimers, and the nonfunctional mutant protein heterodimerize with the wild-type protein inhibiting its function. The HIES is a multisystem disorder affecting dentition, facial features, and immunity (108,109). The disease has also been reported in association with osteogenesis imperfecta (118). There is an autosomal-recessive HIES that is caused by mutations in DOCK8 (119), and TYK2 (120,121); despite the name, these patients have an entirely different disorder with no somatic (no bony and connective tissue problems) who also have recurrent viral infections that are not characteristic of the classical autosomal-dominant HIES. Granulocyte motility has not been studied in these patients.

**82.4.4.3 Diagnosis and Differential Diagnosis.** Patients with chemotactic disorders usually have similar clinical manifestations, with recurrent cutaneous abscesses, mucocutaneous candidiasis, pneumonia, and otitis media. These disorders may be assessed using an in vivo Rebuck skin window test (122), or by an in vitro Boyden chamber chemotaxis (103). A chemotactic defect due to deficiency of cell-surface receptors can be detected by flow cytometric analysis of adhesion molecules or by protein electrophoretic analysis of glycoproteins. CHS can be diagnosed by clinical features as this syndrome has a defect in degranulation, resulting in giant granules in granule-containing cells, partial albinism, and neurologic deficits (88). Chemotaxis defects due to extrinsic suppressing factors can be individually diagnosed based on individual deficits. For instance, patients with leprosy, cirrhosis, and sarcoidosis have been reported to have chemotactic defects based on the presence of a chemotactic factor inactivator. Several bacteria have been shown to produce inhibitors or enzymes capable of destroying complement-derived chemotactic factors, including *Capnocytophaga* (123) and group A and B streptococci (124). In addition, patients showing intractable eczema associated with recurrent cold abscesses should be tested for serum IgE to confirm the diagnosis of the HIES. A high titer of specific IgE directed against *Candida albicans* and *Staphylococcus aureus* is also suggestive of the disorder.

The HIES (Job syndrome) must be differentiated from atopic dermatitis associated with secondary infections

(125). Patients with HIES (102) frequently have cold abscesses in addition to intractable eczema and hyper-IgE (116,126,127). There are characteristic abnormalities in facial features in the patients (105). Secondary infections associated with atopic dermatitis are usually more superficial and show erythema and swelling, and are painful but not cold. Moreover, HIES (Job syndrome) patients often have severe sinopulmonary infections.

**82.4.4.4 Management.** Although complete correction of a granulocyte chemotactic defect has not been accomplished, partial correction in certain patients has been carried out in vitro and in vivo. C5 dysfunction in Leiner syndrome was reported to be corrected by replacement with fresh plasma that contained normal C5. Development of periodontitis and loss of teeth can be minimized in Papillon-Lefevre syndrome with close dental care and prophylactic antibiotics. The treatment of keratoderma is usually based on topical anti-inflammatory emollients and keratolytic agents. Severe pyogenic complications such as liver abscess are possible (128). Vitamin C has been shown to enhance chemotaxis of granulocytes obtained from patients with CHS (129). Studies from our laboratory have shown that IFN- $\gamma$  can enhance chemotaxis of granulocytes obtained from patients with HIES in vitro (130). A small limited clinical trial in four patients with HIES (131) suggested some beneficial clinical effects of IFN- $\gamma$ . Clearly, controlled clinical trials of this recombinant human cytokine are indicated in this disorder. High doses of vitamin C or E have also been reported to be beneficial in some patients. Other strategies, such as cromoglycate and intravenous immunoglobulin, also have been tried in some patients with this disease (132,133). We have also had a Job patient treated with peripheral blood stem cell transplantation for lymphoma, which corrected several of the immunologic features of the disease (134), but it failed in another case (135). More recently, Goussetis et al. (136) reported two unrelated boys with sporadic HIES complicated by high-grade non-Hodgkin lymphoma, who were cured with myeloablative HLA-matched sibling BMT. The autosomal-recessive Hyper-IgE or DOCK8-deficiency is successfully treated with BMT (137–139).

## 82.4.5 Disorders of Phagocytic Uptake

The mechanism by which phagocytes ingest microorganisms involves two distinct stages: adhesion and internalization. Adhesion of targets to phagocytes is through receptors such as Fc and complement receptors, as well as lectin-like receptors (16,23). As described earlier, membrane adhesive glycoproteins, including CR3 and the fibronectin receptor, have been shown to promote the adhesion process. Internalization results from a zipper process, in which circumferential attachment of phagocyte receptors to the ligands (targets) induces engulfment.

**82.4.5.1 Clinical Features.** Disorders of phagocytic uptake are usually secondary to infections, drugs, alcohol, and systemic diseases. Primary defects in phagocytic uptake are rare. Patients with LAD have defects in particulate-mediated phagocytosis (63). Granulocytes from a patient with actin dysfunction failed to polymerize actin, resulting in chemotactic and phagocytic defects (140).

**82.4.5.2 Genetics of Phagocyte Actin Dysfunction.** A congenital phagocytic defect occurs in actin dysfunction, a hereditary disorder with impaired actin polymerization during phagocytosis and movement. Granulocytes obtained from the patient's parents show retarded actin polymerization (141), although not the profoundly impaired actin polymerization seen in the patient, suggesting that this disease is an autosomal-recessive disorder. Some believe that this disorder may actually have been a case of LAD-I. WASP deficiency causes macrophage deficiency at several levels, including morphology (142), adhesion defects (143–146) chemotactic defects (147), and phagocytic defects (148–151).

**82.4.5.3 Diagnosis and Differential Diagnosis.** Most phagocytic defects are secondary to endogenous cytokines, exogenous drugs, and infections. Before making a diagnosis of an intrinsic phagocytic defect, one should rule out extrinsic defects, as well as other phagocyte function defects. A  $2 \times 2$  factorial design can be used to make a differential diagnosis. The patient's and control's granulocytes are incubated with bacteria opsonized with autologous or heterologous serum to differentiate intrinsic phagocytic defect from serum factor abnormalities. Latex-coated particles, as well as antibody- and complement-coated targets, are traditionally utilized to test phagocytosis under a microscope. Using a fluorescein isothiocyanate (FITC)-labeled technique, phagocytosis can be assessed with a flow cytometer. FITC-labeled bacteria ( $1 \times 10^7$  cfu/mL), which are heat-killed (70°C for 60 min) and labeled with 0.03% FITC (Sigma Co.) at room temperature for 2 h, are incubated with normal or patient's granulocytes ( $2 \times 10^6$  cells/mL) in the presence of 0.1 volume of human serum at 37°C for 30 min. Results are read with a flow cytometer after washing twice and fixing in 1% paraformaldehyde.

**82.4.5.4 Management.** Primary defects in phagocytic uptake are rare. Lack of evidence of the underlying defect in the minimal number of cases with primary phagocytic defects limits the approach to treatment in disorders of phagocytic uptake. Studies with normal granulocytes have recently shown that several cytokines and glycoproteins enhance motility and phagocytic uptake (152–154). Such cytokines and glycoproteins may be candidates for treatments in these phagocytic disorders. Treatment of patients with secondary phagocytic defects is based on the individual deficits. For example, patients with phagocytic defects due to opsonin deficiency, such as antibody, can be infused with intravenous gamma globulin. For those with a relative cytokine

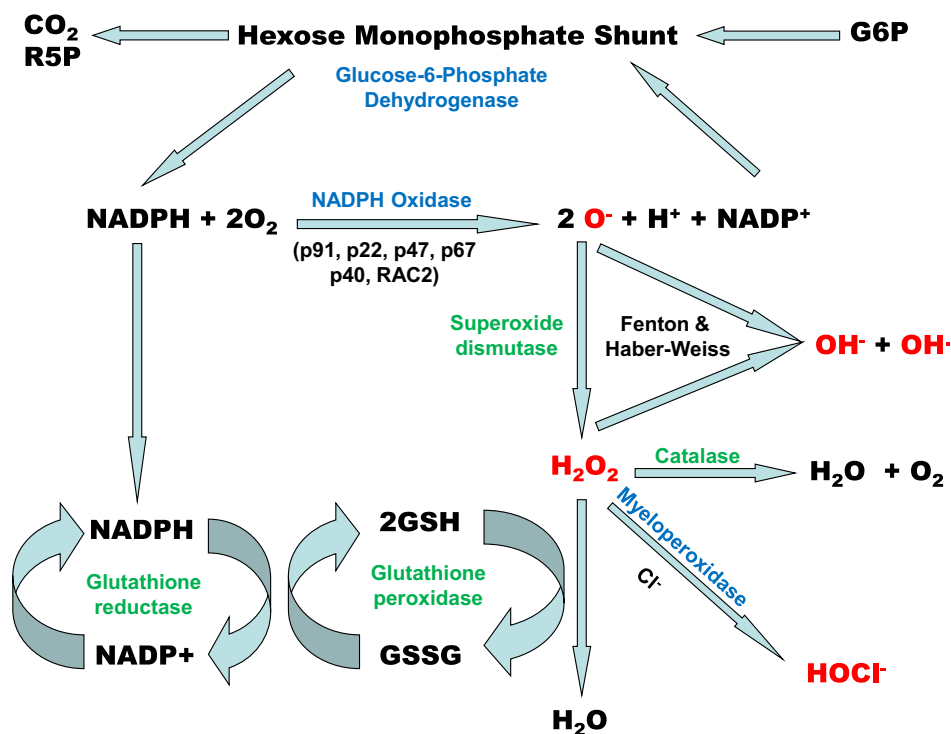

(e.g. IL-12, IFN- $\gamma$ ) deficiency, specific correction with recombinant cytokine may reverse the immune dysfunction (155,156). In addition, as with other granulocyte function disorders, patients with phagocytic defects may sometimes acquire life-threatening infections, so that antibiotics or granulocyte transfusion may be required in certain situations.

### 82.4.6 Disorders of Oxygen-Dependent Microbicidal Activity

In response to soluble or insoluble stimuli, granulocytes are induced to increase chemokinesis, adhesion, chemotaxis, and phagocytic uptake. In addition, these stimuli simultaneously cause respiratory burst activation and degranulation. Granulocytes with defects in respiratory burst activity usually have normal adhesion, chemotaxis, and phagocytic uptake, but abnormal intracellular microbicidal activity. These disorders include CGD, glucose-6-phosphate dehydrogenase (G6PD) deficiency, MPO deficiency, and glutathione

synthetase deficiency. Respiratory burst activity associated with phagocyte activation is elicited by NADPH oxidase, which is composed of a flavoprotein, a ubiquinone, and cytochrome b558 (Figure 82-1). The NADPH oxidase, in conjunction with certain cytosolic factors, serves to transport an electron from NADPH to  $O_2$ , resulting in  $O_2$ -formation (reviewed in Yang and Hill (23)). Defects in any component of the oxidase (seen in patients with CGD), as well as defects associated with generation of the cofactor NADPH (seen in severe leukocyte G6PD deficiency) or impaired NADPH regeneration (seen in glutathione synthetase deficiency), may cause a deficiency in oxygen-dependent microbicidal activity.

**82.4.6.1 Clinical Features.** Patients with defects in oxygen-dependent bactericidal activity suffer from recurrent cutaneous, organ, and tissue abscesses and recurrent sinopulmonary infections. Granulomas may form at the site of tissue infections, resulting in obstructive disorders involving the gastrointestinal and urinary systems. Lymphadenitis and osteomyelitis are not uncommon.

**FIGURE 82-1** Respiratory burst pathways in the phagocyte system. The hexose monophosphate shunt is a process that generates NADPH and pentoses (Ribulose-5-Phosphate or R5P) from glucose-6-phosphate (G6P). G6P dehydrogenase is part of the hexose monophosphate shunt, and a critical step for NADPH generation. NADPH oxidase generates superoxide anions ( $O_2^-$ ) from NADPH and oxygen. The neutrophil NADPH oxidase function requires six protein subunits (p91, p22, p47, p67, p40, and RAC2), mutations in five of which are known to cause chronic granulomatous disease. Upon phagocyte activation, cytosolic factors are translocated into the plasma membrane components composed of p91phox and p22phox. Hydrogen peroxide ( $H_2O_2$ ) is generated from superoxide anion by superoxide dismutase. Myeloperoxidase produces hypochlorous acid (HOCl) from  $H_2O_2$  and chloride anion ( $Cl^-$ ). Reduction of  $H_2O_2$  can also be mediated by iron (or copper) in the Fenton reaction generating hydroxyl radicals ( $\cdot OH$ ). The Haber-Weiss reaction (superoxide anion plus hydrogen peroxide) produces  $OH^-$  and  $\cdot OH$ . Antioxidative systems are shown in green. Antioxidative systems are critical as reactive oxygen species damage not only pathogens but cellular DNA and membranes as well. The reactive oxygen species are shown in red. Critical enzymes required for primary phagocyte defects are highlighted in blue. GSH is reduced glutathione, GSSG reduced glutathione.

Infections are most often due to catalase-positive microorganisms.

#### 82.4.6.2 Genetics.

**82.4.6.2.1 Genetics of CGD.** The phagocyte-specific NADPH oxidase (NOX2) is a member of a ubiquitous family of NADPH oxidases (NOX1-5, DUOX1-2). The neutrophil NADPH oxidase is composed of two membrane and four cytosolic components. Studies in a cell-free system indicate that superoxide production requires the participation of both membrane-bound oxidase (NADPH oxidase) and cytosolic factors. Two-thirds of CGD cases are transmitted in an X-linked recessive pattern owing to the absence or inadequate function of cytochrome b558 heavy chain (p91phox, encoded by CYBB), a component of the NADPH oxidase complex (also known as NOX2) located on the short arm of the X chromosome (Xp21.1). The rest are inherited by an autosomal-recessive mechanism and are due to the absence of cytochrome b558 light chain (p22phox, encoded by CYBA) or one of the cytosolic factors necessary for NADPH oxidase activation. The gene coding for cytochrome b558 light chain (p22phox) is located on chromosome 16q24, whereas those encoding the cytosolic factors p47phox and p67phox are located on chromosomes 7q11.23 (neutrophil cytosolic factor 1 or NCF1) and 1q25 (neutrophil cytosolic factor 2 or NCF2), respectively (10). The cytosolic p40phox and Rac2 GTPase are also required for the neutrophil NADPH oxidase function. p40phox stimulates phagocytosis-induced NADPH oxidase activity via a phox homology (PX) domain that binds to phosphatidylinositol-3-phosphate (PtdIns(3)P) that accumulates on phagosomes. Rac2 (22q13) is involved in the control of the neutrophil actin cytoskeleton, cell migration, in addition to the NADPH oxidase (157). Mutations in p47phox are found in about 30% of CGD patients. Mutations in p22phox and p67phox each result in <5% of CGD cases. Only one CGD patient is described with a mutation in NCF4 (neutrophil cytosolic factor 4; 22q13) that encodes p40phox (158). Rac2 mutations have not been reported as a cause of CGD, but one patient with mutation in Rac2 was reported (159,160); this patient presented with severe bacterial infections and poor wound healing and had a partial oxidase defect, impaired leukocyte migration, adhesion, degranulation and superoxide anion production, a clinical picture somewhat resembling that of leukocyte adhesion deficiency.

The nature (e.g. missense, nonsense, frameshift, deletion, splicing; (161,162)) and exact location of the mutations in the various components of the NADPH oxidase is critical. A recent study demonstrated a strong genotype–phenotype correlation in CGD as the residual NADPH oxidase activity determines the severity of morbidity and mortality (163). As the clinical presentation is varied and dependent on the degree of NADPH oxidase system deficiency, some CGD results in a less-severe phenotype presenting later in life. These variant CGDs

are more difficult to diagnose, but this form is becoming more readily recognized based on improved flow cytometry and DNA-based testing methods (164,165). It is also important to note that the phagocyte NADPH oxidase (NOX2) is not neutrophil specific as the NADPH oxidase is also expressed in monocytes, macrophages, B cells and dendritic cells, and the deficiency in these cells is not understood. It appears that some mutations in p91phox might mainly manifest as macrophage deficiency leading to X-linked predisposition to mycobacterial infection (166).

**82.4.6.2.2 Genetics of Leukocyte G6PD Deficiency.** G6PD deficiency is the most common enzyme deficiency in humans, with over 140 different mutations described (167,168). The most common mutations (seen in patients with Africans ancestry) lead a mild-to-moderate enzyme deficiency (20–60% activity) and to intermittent hemolysis usually secondary to infections or drugs. Few patients with severe forms of G6PD deficiency present with a CGD-like clinical picture. Profound deficiency of G6PD leads to a defect in NADPH production, causing impaired respiratory burst activity (Figure 82-1). The gene coding for this G6PD enzyme is located on Xq28 (169). The G6PD enzyme is a heterodimer, each monomer (molecular weight, 56,000) being associated with an NADP<sup>+</sup> molecule. This enzyme has a widely variant polymorphism in different populations in the world. Studies in blacks and whites have shown that whites with G6PD deficiency more often have affected leukocytes (170,171). G6PD deficiency in leukocytes is encoded by the same gene as that in erythrocyte precursors and other tissues. G6PD activities in leukocytes are usually higher than those in erythrocytes, so that patients with G6PD-deficiency-associated hemolytic anemia usually have normal leukocyte function. Only leukocytes with <20% (particularly <5%) of normal G6PD activity show abnormal bactericidal activity. Whether there are unknown factors in leukocytes from different races that could affect G6PD activity remains to be determined as patients with G6PD deficiency associated with the CGD-like syndrome have been reported in white, but not in black or Mongolian populations.

**82.4.6.2.3 Genetics of Glutathione Synthetase Deficiency.** As shown in Figure 82-1, glutathione levels are modulated by NADPH, glutathione reductase, and glutathione synthetase. Granulocytes with glutathione reductase or glutathione synthetase deficiency have a normal early respiratory burst, whereas subsequently continuous production of toxic oxygen products, which are normally handled by glutathione, results in auto-oxidative damage and defective microbicidal activity (172) (reviewed by Yang and Hill (173)). About 30 different mutations in the GSS gene have been identified. Genotype–phenotype correlations studies demonstrated that the mildly affected (based on enzymatic activity) patients have isolated hemolytic anemia, this is compounded with metabolic acidosis in moderately

affected patients, whereas the severely affected patients also have progressive dysfunction of the central nervous system. Excretion of 5-oxoproline in the urine is present in almost all patients (174). Both glutathione reductase and glutathione synthetase deficiencies are transmitted by autosomal-recessive inheritance. The gene coding for glutathione reductase is mapped to chromosome 8p21.1 (175,176). The gene encoding human glutathione synthetase maps to chromosome 20q11.2 (177). Patients with glutathione reductase deficiency can have hemolytic crises and usually abnormal phagocyte bactericidal activity. In contrast, patients with glutathione synthetase deficiency show abnormal bactericidal activity, in addition to having erythrocytes susceptible to hemolysis. Patients with the latter disease are more susceptible to bacterial infections because phagocyte activation is associated with an increase in intracellular hydrogen peroxide, with a low level of glutathione synthetase resulting in auto-oxidative damage to the cell.

**82.4.6.2.4 Genetics of MPO Deficiency.** Granulocytes in MPO deficiency have normal production of superoxide, but defective generation of hypochlorite ion. Patients with this disorder are not uncommon (1 in 2000 to 1 in 4000 in the general population), but are frequently asymptomatic or at most have delayed granulocyte killing activity and recurrent candidal infections (173,178). The MPO gene is located on chromosome 17q23.1 (179) that encodes the azurophilic granule-localized MPO. MPO uses heme as a cofactor to oxidize chloride to the +1 state forming HOCl. Candidal infections have been observed in MPO-deficient patients with diabetes mellitus, although the frequency is <5% of reported MPO-deficient patients (180). Some studies also demonstrated that complete MPO deficiency has a higher incidence of malignancies (180). MPO deficiency is inherited as an autosomal-recessive trait (181–183). A study of the MPO protein messenger RNA and complementary DNA simultaneously indicates the existence of diverse abnormalities in patients with MPO deficiency (184). Certain patients have MPO-expressing defects originating from a regulatory mutation that induces the MPO gene to switch off at an early stage of phagocyte differentiation (185).

**82.4.6.3 Diagnosis and Differential Diagnosis.** Patients with CGD have normal phagocytic uptake but abnormal oxygen-dependent intracellular killing, resulting in recurrent abscesses, lymphadenitis, and granuloma formation. Catalase-positive microorganisms, such as *S. aureus*, *Escherichia coli*, *Serratia marcescens*, *Aspergillus*, and *Candida*, are the common pathogens in patients with CGD and CGD-like diseases. In contrast, organisms such as streptococci seldom cause infection as the hydrogen peroxide generated by these organisms can interact with Cl<sup>-</sup> in the presence of MPO from phagocytes to form hypochlorite ion (OCl<sup>-</sup>), resulting in killing of bacteria. The laboratory diagnosis of CGD is usually made by assessing the phagocyte respiratory burst by

flow cytometric analysis using dihydrorhodamine123 (DHR) fluorescence (148). Nitroblue tetrazolium dye reduction should no longer be used for CGD diagnosis because of this tests failure to adequately screen for autosomal-recessive or variant-linked CGD.

A decrease in luminol-dependent chemiluminescence associated with elevated lucigenin-mediated chemiluminescence can be used to screen for patients with MPO deficiency, as lucigenin-mediated chemiluminescence is used to reflect superoxide production and luminol-mediated chemiluminescence is used to reflect MPO activity (186). In addition, assessment of granulocyte bactericidal activity using a bacterial colony formation assay is also applicable (3). The flow cytometric DCFH or DHR assay that is used for diagnosing CGD is positive in complete MPO deficiency, but eosinophils from MPO-deficient individuals retain eosinophilic peroxidase, and therefore, generate a normal DHR signal (187).

**82.4.6.4 Management.** The cellular and molecular bases of disorders related to oxidative microbicidal activity have been extensively explored (Figure 82-1). Pharmacologic approaches to treating CGD have been tried for three decades. Most of these therapies have been partially successful or controversial (188). Chronic prophylaxis with trimethoprim–sulfamethoxazole at 5 mg/kg of trimethoprim daily decreases the numbers of bacterial infections (189). In contrast, there is concern about an increased risk of fungal infections, especially *Aspergillus*. Fortunately, the data from Margolis et al.'s study (189) did not warrant this concern. Other troublesome infections for the CGD patients are due to fungi, especially *Aspergillus* lung and bone infections that usually require several months of antifungal therapy. An antifungal drug, itraconazole, has been used for *Aspergillus* prophylaxis and is reported to be effective (190). More recently, other azols, such as voriconazole, have utilized but are much more expensive.

Studies have also shown that recombinant IFN- $\gamma$  in a low dose (50  $\mu$ g/m<sup>2</sup>) administered subcutaneously three times a week significantly reduces serious infections in patients with CGD (191–193). Initial in vitro and in vivo studies in CGD patients suggested that phagocytes that do not normally release superoxide in response to stimuli did release small amounts of superoxide after treatment with IFN- $\gamma$  (191,193). This enhancement of superoxide generation by IFN- $\gamma$  treatment could not be confirmed in a large controlled trial, but there was a 70% reduction in infectious complications among the participants treated with this agent (192). BMT in CGD patients has been reported to result in long-term chimeric engraftment with a decrease in infectious complications (194). Despite important advances in supportive therapy, CGD remains a potentially lethal disease. The only curative approach, which is being utilized more frequently with success, is allogeneic stem cell transplantation. A recent approach with donor lymphocyte infusion after nonmyeloablative allogeneic peripheral blood stem cell transplantation

for CGD appears to be promising, showing fewer graft-versus-host reactions (195). Following detection of the genes coding for CGD (196,197), attempts at gene therapy for the disease have been made with vector gene transfer (198,199), but the first corrections have been short lived. Newer attempts demonstrated clinical benefits, such as successful clearance of *Aspergillus* infections, but one of the two patients developed a myelodysplastic syndrome and died (200–202). The latest gene therapy trial treated three gp91mutant patients and achieved long-term correction of neutrophil oxidase function in two (203).

Glutathione synthetase deficiency can be partially corrected by administration of vitamin E (204). Patients with MPO deficiency are usually asymptomatic; however, for those developing chronic candidiasis, ketoconazole or fluconazole can be used.

### 82.4.7 Disorders of Oxygen-Independent Bactericidal Activity

Oxygen-independent microbicidal defects can arise from the absence of granules or from defective degranulation. Several patients with an absence of specific granules have been described as specific granule deficiency. Studies with granule-deficient granulocytes show impaired bactericidal activity in addition to impaired chemotaxis (87). HPS, Chediak–Higashi syndrome and GS are all lysosomes and lysosome-related organelle deficiencies (205). All these diseases can also lead to neutropenia and are listed in Table 82-1. The reason for granulocyte dysfunction in these patients is the failure of granule constituents to fuse with the phagosome. The defective protein in Chediak–Higashi syndrome is involved in the lysosomal fusion, resulting in defects of both degranulation and membrane regeneration (89,206). This subsequently decreases oxygen-independent bactericidal activity and the expression of adhesion molecules and chemotactic factor receptors on the cell surface. CHS has a defect in transportation of granules, affecting all granule-containing cells, such as melanocytes, neurons, and granulocytes. This syndrome is characterized by partial albinism, granulocytopenia, neurologic deficits, recurrent infections, and poor ADCC against tumor cells. There are also defects in neutrophil chemotaxis and bactericidal activity. Another similar granule-transporting defect showing hypopigmentation and immunodeficiency, called GS, was first described in 1978 (207). It is now known to involve a defect of one of the two genes called MYO5A (myosin V) and RAB27A that control movement of melanosomes. MYO5A is expressed in the nervous system, but RAB27A is expressed in the skin and immune cells (208). Most GS cases are reported from Turkish and Mediterranean populations. Mutations in eight genes are known to cause HPS (HPS1–8). HPS2 is the only one HPS gene, in which mutations lead to immune deficiency (209). The secretory lysosomes of HPS-2 mutant cells fail to polarize upon activation (210).

**82.4.7.1 Genetics.** Patients with specific granule deficiency have autosomal-recessive inheritance caused by mutations in CCAAT/enhancer-binding protein epsilon (C/EBPE) gene (211–213). Heterozygous siblings or parents usually have a normal phenotype. Similarly, patients with CHS have an autosomal-recessive trait. Affected victims have parents with normal phagocyte function, but there may be a history of intermarriage. The human CHS gene maps to chromosome 1q42–q43 (90,214). GS involves albinism, granulocytopenia, and immunodeficiency encoded on chromosome 15q21 (95). The first genetic defect identified in GS (type 1; MIM 214450) was the gene, which encodes the actin-associated myosin Va motor protein (MYO5A). Subsequently, RAB27A was cloned for GS type 2 (MIM 607624; (215)). These two genetic defects have similar skin manifestations but distinct pathologic findings in the neurologic system (208). Griscelli syndrome type 3 (GS3) (MIM 609227) is caused by mutations in Melanophilin (MLPH; (216)).

**82.4.7.2 Diagnosis and Differential Diagnosis.** Diagnoses of the granule deficiency syndromes are based primarily on clinical manifestations as well as granulocyte morphology, with absence of specific granules (217). Furthermore, granulocytes from patients with specific granule deficiency do not release certain constituents from specific granules, and show a defect in membrane recycling of adhesion molecules and chemotactic factor receptors. The constituents inside specific granules, such as transferrin and vitamin-B12-binding protein, can be detected by enzyme-linked immunosorbent assay and radioimmunoassay, respectively (87). Three intracellular organelle trafficking defects have recently been identified, including CHS, GS, and oculocutaneous albinism (89,94). Patients with these syndromes all have hypopigmentation (albinism) and granulocytopenia. In addition to these symptoms, patients with CHS have recurrent infections, neurologic deficits, neoplastic transformation, altered membrane fusion associated with giant azurophilic granules, and defective chemotaxis, degranulation, and bactericidal activity (129). GS involves albinism and immunodeficiency, including neutropenia, thrombocytopenia, and T- and B-cell defects. Defects in MYO5A, known as GS-I, cause neurologic pathology in addition to skin hypopigmentation and immunodeficiency, and defects in RAB27A, known as GS-II, cause partial albinism and immunodeficiency but not neural deficits (208). Molecular diagnosis of CHS and GS may be available as the genes have been mapped to chromosomes 1q42–43 and 15q21, respectively (89,94). The third form of GS (GS-III) is restricted to hypopigmentation without immunodeficiency (216).

**82.4.7.3 Management.** There is no specific treatment for patients with deficiency of specific granules as only a limited number of cases have been described. Palliative treatment with antibiotic prophylaxis and granulocyte transfusion may be indicated. Bactericidal

defects in CHS have been shown to be improved following the administration of large doses of vitamin C. This may reduce the intracellular cAMP level, resulting in improvement in chemotaxis and bactericidal activity (129). Experimental evidence suggests that administration of G-CSF (10 µg/kg) can improve CHS-associated granulocytopenia, chemotaxis, and phagocytosis in an animal model (218). Currently, BMT may be the best way to treat patients with this syndrome although BMT only treats the hematologic and immunological defects, the neurological problems remain (219). In the future, the possibility of gene therapy for CHS and GS must be considered as the genes for these disorders have been well characterized as described earlier.

## 82.5 MONOCYTES/MACROPHAGES FUNCTION DISORDERS

Monocytes/macrophages share the same ancestor cells as granulocytes, so that most of the functional defects present in granulocyte function disorders occur in monocytes/macrophages, including LAD, phagocyte actin dysfunction, respiratory burst defects such as CGD, degranulation defects such as CHS, and specific granule deficiency. Monocytes/macrophages are also involved in antigen presentation, especially dendritic cells derived from monocytes that have TLRs on their surfaces that are used to recognize microbes and mediate signals. These serve as the link between innate and adaptive immunity (43,45,220). Primary macrophage function defects are relatively rare; most of the macrophage function defects are secondary. The function of monocytes/macrophages can be compromised by environmental agents, drugs, infections, and metabolic disorders resulting in functional defects. For instance, smoke, asbestos, silica, hyperbaric oxygen, and air pollution can impair macrophage function. In addition, monocytes/macrophages can be seriously impaired in patients with human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS). Differential induction of cytokines may contribute to the resistance or susceptibility of macrophages to infections with intracellular organisms (156). Monokine enhancement of HIV infection and defective antigen presentation by monocytes have been implicated in patients with both AIDS and tuberculosis. CD40-ligand-mediated monocyte chemotactic proteins and RANTES production by monocytes and dendritic cells may contribute to suppression of HIV infections (221,222). Deficiencies of certain cytokines and their receptors, such as IL-12, IL-12 receptor, and IFN-γ receptor (IFN-γR), can cause impaired intracellular bactericidal defects resulting in mycobacterial infections and repeated salmonellosis (31,155,223,224). Monocytes obtained from patients with chronic mucocutaneous candidiasis show impaired chemotactic activity owing to defects in lymphocyte-derived cytokines. Similarly, monocytes obtained from a patient with common variable hypogammaglobulinemia

have been shown to have impaired antigen presentation to T cells (225), which could be a primary or secondary monocyte function defect. In summary, four types of primary macrophage function defects have been identified, including osteoporosis, TLR signaling deficiency, IFN-γR deficiency, and familial lysosomal storage diseases.

### 82.5.1 Clinical Features

Monocytes, dendritic cells, and macrophages have different functions in different tissues. Thus different monocyte/macrophage function defects have quite different clinical features. Osteopetrosis is due to dysfunction of osteoclasts (specialized macrophages), resulting in impaired resorption of mineralized cartilage and bone remodeling. The abnormal encroachment of sclerotic bone can compromise the nerve foramen and bone marrow space, resulting in neurologic and hematopoietic defects. Although monocytes from osteopetrosis patients may show normal or minimally impaired phagocyte function, BMT can rapidly reverse abnormal osteosclerotic changes and reconstitute immune function, which suggests that this specialized macrophage (osteoclast) defect may result in this disease (226). Pulmonary alveolar proteinosis (PAP) is characterized by pulmonary surfactant accumulation leading to respiratory distress and potentially respiratory failure (227). Surfactant catabolism requires the activation of alveolar macrophages by GM-CSF. PAP can be secondary but may also result from a primary genetic defect of the GM-CSF receptor α gene on the X chromosome (228–230).

Monocytes and dendritic cells have at least 10 TLRs (43,45,220). Different TLRs can recognize different microorganisms or microbial products, and mediate signals for innate immunity and adaptive T-cell differentiation (43,45,47). Patients with defects in different TLRs may be prone to certain types of infections. In an animal model, deficiency of TLR-4 results in altered allergic-type reactions (231). A defect in IL-12 production by the monocyte-series cells leads to impaired IFN-γ production, resulting in mycobacterial and *Salmonella* infections (155,223). The clinical features are also similar to those in patients with IFN-γR deficiency. The atypical tuberculosis in IL-12 or IL-12 receptor deficiency tends to be accompanied by granuloma formation (155,223). In contrast, patients with IFN-γR deficiency usually have poorly formed granulomas (31,224).

Another group of hereditary macrophage function defects include the metabolic storage disorders, especially those with lysosomal enzyme deficiencies. The accumulation of lipid or polysaccharide in the macrophages may lead to the development of foam cells and defective catabolic functions. The fact that metabolic storage diseases have been successfully treated by BMT (232) suggests that the macrophage catabolic defect may have a critical role in the pathogenesis of these diseases.

A number of primary immunodeficiencies that mainly manifest in other cells also affect monocytes and macrophages. Primary defects in neutrophils, such as CGD and leukocyte adhesion deficiency, often affect monocytes and macrophages. Some NADPH oxidase mutations, for example, might not even present as CGD, but as a monocyte macrophage defect (166,233). Chemotaxis defects such as Papillon–Lefèvre syndrome involve both myeloid lineages. Crohn’s disease is traditionally thought as an autoimmune disease, but some research suggests that CD could be primary immunodeficiency of macrophages: macrophages fail to attract neutrophils to mucosal injuries to ensure local acute inflammatory response and immunity leading to the development of chronic, granulomatous disease (234).

### 82.5.2 Genetics

Osteopetrosis is a hereditary disease transmitted by an autosomal-recessive trait (osteopetrosis congenita), which occurs in infants and children, but some cases are mediated by an autosomal-dominant trait (osteopetrosis tarda), which occurs in adults. The healthy bone is maintained by a dynamic balance of bone formation and resorption. The mesenchymal osteoblasts synthesize the bone and the hematopoietic-derived osteoclasts are responsible for bone resorption. The autosomal-recessive osteopetroses can be divided into two groups, one with a deficient number of osteoclasts and another with normal or increased number of nonfunctional osteoclasts. AR osteopetrosis patients die before the age of 6 years, mostly due to recurrent infections. This disorder is more commonly seen in the offspring of consanguineous parents. Five genes are known to be causative for AR osteopetrosis. The underlying gene in most patients is TCIRG1, which encodes the 116-kD subunit of the vacuolar proton pump (235), but mutations in the CLC-7 chloride channel (236), OSTM1 (Gray-lethal; (237,238)), PLEKHM1 (239), TNFSF11 (encoding RANKL (receptor activator of NF- $\kappa$ B ligand); (240)) or mutations in TNFRSF11A (encoding RANK (241)) all lead to osteopetrosis. Osteopetrosis due to mutations in RANK also leads to hypogammaglobulinemia (241). A rare X-linked recessive anhidrotic ectodermal dysplasia with osteopetrosis and immunodeficiency is caused by mutations in IKBKG gene (encoding NEMO, [MIM 300248]; (242)). An autosomal-dominant form of anhidrotic ectodermal dysplasia with T-cell immunodeficiency is caused by gain-of-function mutation of IKBA, resulting in impaired activation of NF- $\kappa$ B (243).

Studies in a mouse model of osteopetrosis indicate that a defect in the M-CSF gene contributes to abnormal bone resorption and macrophage differentiation (244). The M-CSF gene maps to chromosome 1p21 in humans, but was excluded as the disease-causing gene in patients with autosomal-dominant osteopetrosis (245). A gene close to the M-CSF gene in the 1p21 region is

proposed (245). Prenatal diagnosis by fetal sonography may be made through the recognition of sclerotic, dense, narrow, and radiopaque bones. Osteopetrosis can also accompany leukocyte adhesion deficiency type III caused by mutations in KINDLIN3 (FERMT3; (246)). Carbonic anhydrase II (CAII) deficiency syndrome is characterized by osteopetrosis (OP), renal tubular acidosis (RTA), and cerebral calcifications (247).

Primary immunodeficiency with pneumococcal and streptococcal infections due to TLR signal deficiency has been reported (248). A mutation of the interleukin-receptor-associated kinase-4 (IRAK-4) that is responsible for TLR activation can lead to repeated bacterial infections and poor antibody responses (249). The bridge between the TLRs and IRAK signaling complex is the myeloid differentiation factor (MyD)88. The clinical features of myeloid differentiation factor (MyD)88 deficiency are indistinguishable from IRAK-4 deficiency (250,251). All human TLRs other than TLR3 use both MyD88 and IRAK-4. Several IRAK members are responsible for IL-1 and TLR signaling, but it remains unclear whether all the IRAK family members are involved in TLR signaling and in the host defense against bacteria or viruses.

Macrophage phagosomes are both the site of elimination of mycobacteria and the site of mycobacterial replication. Mendelian susceptibility to mycobacterial diseases (MSMD) are caused by deficiencies in the IL-12/IL-23/IFN- $\gamma$  cytokines and their signaling pathways. IL-12 is produced by antigen-presenting cells in response to infection. IL12B encodes the p40 subunit shared by IL-12 and IL-23. IL12RB1, encodes the beta 1 subunit shared by the IL-12 and IL-23 receptors (IL-12Rb1). IL-12 induces IFN- $\gamma$  production, among others. IFNGR1, encodes the ligand-binding chain of the IFN- $\gamma$  receptor (IFN- $\gamma$  R1); IFNGR2 encodes the associated chain of the IFN- $\gamma$  receptor (IFN- $\gamma$ R2); STAT 1 encodes the signal transducer and activator of transcription-1 (STAT 1) in the IFN- $\gamma$  receptor signaling pathway. Interestingly, the autosomal-recessive form of STAT1 deficiency leads to susceptibility to both mycobacteria (IFN- $\gamma$ -mediated immunity) and viruses (IFN- $\alpha/\beta$ -mediated immunity), whereas the autosomal-dominant STAT1 deficiency leads to MSMD only. NEMO is a regulatory subunit of the NF- $\kappa$ B (NF $\kappa$ B) inhibitor kinase complex, and required for IL12 production, NEMO deficiency is an X-linked MSDS. Mutations in IFN- $\gamma$ R1 (OMIM 107470; (252,253)), IFN- $\gamma$ R2 (OMIM 147569; (254)), STAT1 (OMIM 600555; (255)), IL-12p40 (OMIM 151561; (155,256)), IL-12Rb1 (OMIM 601604; (257)), and NEMO (OMIM 300248) genes lead to susceptibility to mycobacterial and *Salmonella* infection. Tyrosine kinase 2 (TYK2) deficiency (OMIM 611521) leads to sensitivity to mycobacterial and *Salmonella* infections in addition to other viral, bacterial and fungal infection and elevated serum IgE (120); this likely represents an autosomal-recessive form of HIES.

Macrophage function defects in certain lipid storage diseases due to lysosomal enzyme deficiencies, such as Niemann–Pick disease, Gaucher disease,  $G_{M1}$  gangliosidosis type I, and Fabry disease, usually involve macrophage catabolic defects, with the formation of histiocytic foam cells containing mucolipids (e.g. sphingolipids) in the reticuloendothelial system, vessels, and visceral organs. Similarly, mucopolysaccharidoses, such as Hurler, Hunter, and Sanfilippo syndromes, have macrophage catabolic defects in addition to dystrophic storage in connective tissues. Mucopolysaccharidoses are also commonly transmitted by autosomal-recessive inheritance, except for Hunter syndrome (iduronate sulfatase deficiency), which is X-linked (Chapter 102).

### 82.5.3 Diagnosis and Differential Diagnosis

Patients with osteopetrosis are usually characterized by having a generalized increase in bone density throughout the body, failure to thrive, and hypocalcemia with low serum phosphate due to impaired bony resorption, as well as a degree of anemia, thrombocytopenia, and leukopenia. A defect in macrophage function could contribute to recurrent infections suffered by these patients in addition to abnormal bony resorption.

Patients with a mutation in IRAK4 and MyD88 are susceptible to bacterial infections, mostly by gram-positive bacteria (e.g. *Streptococcus pneumoniae* and *S. aureus*), with no decreased resistance to fungi, parasites, and viruses (250). Interestingly, those IRAK4 and MyD88 deficient patients who survive childhood improve with age.

A patient with defective TLR signaling associated with recurrent pneumococcal infections revealed impaired IL-6 and IL-12p40 induction by TLR agonists (248).

Patients with IL-12, IL-12 receptor or IFN- $\gamma$ R deficiencies tend to have a similar clinical picture, with disseminated BCG, atypical mycobacterial, and *Salmonella* infections (31,155,223). Patients with IL-12 deficiency can be diagnosed by a decrease in IL-12 production by peripheral mononuclear leukocytes after mitogen stimulation. IL-12 receptor deficiency can be diagnosed by flow cytometric analysis of IL-12 receptor expression on T cells and NK cells. Patients with IFN- $\gamma$ R deficiencies cannot be simply assessed by flow cytometric analysis of IFN- $\gamma$ R expression as many different variant forms have been identified (31,224,253,258). Defective CD64 expression, TNF- $\alpha$  production, and Jak-STAT phosphorylation may be better diagnostic criteria. Of course, direct gene sequence analysis or studies of polymorphism may offer better diagnosis and carrier detection and prenatal diagnosis (258).

The diagnosis of patients with lipidoses and mucopolysaccharidoses is usually based on clinical features,

with characteristic dysmorphism of the face, chest, and extremities, as well as mental retardation and hepatosplenomegaly. The presence of urinary mucopolysaccharides is characteristic. A definitive diagnosis should be based on specific enzyme assays employing cultured fibroblasts and leukocytes. Heterozygous carriers in some of these storage diseases can be detected by showing half of the normal amount of the lysosomal enzyme activity in cultured fibroblasts or leukocytes. Prenatal diagnosis using cultured amniotic cells obtained between 18 and 20 weeks' gestation is also available.

### 82.5.4 Management

Most of the primary macrophage function defects can be effectively treated by BMT, which provides normal macrophage precursors. In certain diseases, exogenous replacement of defective enzyme may be useful. For instance, Hurler syndrome, which is associated with a deficiency of  $\alpha$ -L-iduronidase, can be partially corrected by replacement with the normal enzyme. Takahashi et al. (259) showed that osteopetrosis in a mutant mouse model lacked functional M-CSF activity, which could be partially corrected with exogenous M-CSF. This is not the case, however, in humans with autosomal-dominant osteopetrosis (245). Patients with TLR signaling defects might possibly be treated through early administration of proinflammatory cytokines, such as IL-6 or IL-12, as these patients tend to have poor IL-6 and IL-12 induction (248,249).

Patients with IL-12 deficiency may be treated with exogenous IL-12 or IFN- $\gamma$  supplementation. Those with IL-12 receptor deficiency can be treated with exogenous IFN- $\gamma$  as this promotes intracellular killing of mycobacteria (155,223). Patients with IFN- $\gamma$ R deficiency frequently show persistent infections with atypical mycobacteria and disseminated BCG infections, which do not respond to antibiotics or IFN- $\gamma$  and TNF (31). On the basis of genetic polymorphism, carrier detection and prenatal diagnosis may be available (258), and gene therapy may be possible in the future.

Dietary calcium restriction and high-dose calcitriol have been used to stimulate host osteoclasts to resorb bone. High-dose corticosteroids, erythropoietin and parathyroid hormone can improve hematopoiesis and bone resorption, and hematopoietic stem cell transplantation is an option for osteopetrosis (260). Exogenous RANKL-induced formation of functional osteoclasts from their monocytes, suggesting that they could, theoretically, benefit from exogenous RANKL administration (240).

### 82.5.5 Prevention of Phagocyte Function Disorders

**82.5.5.1 Primary Prevention.** Phagocyte function disorders occur in X-linked, autosomal-recessive, and autosomal-dominant patterns of transmission or

sporadically. Most are X-linked or autosomal recessive. Primary prevention for such disorders is based on carrier detection. Young people should receive health examinations (including a complete family pedigree) before marriage and be aware of the risks of intermarriage. Carrier detection should be undertaken in major X-linked and autosomal-inherited disorders when available. Several techniques can be used to detect the carrier state: analysis of random X-chromosome inactivation, analysis of chromosome breakage or deletion, RFLP, single-stranded conformational polymorphism followed by direct sequencing, direct measurement of gene products, and cell function assays (261–263). There are several phagocyte disorders for which carrier detection is currently available. Carrier detection in the X-linked form of CGD can be established with a functional assay such as dihydrorhodamine fluorescence (264). LAD can be detected by flow cytometric analysis of the gene product (CD18) using monoclonal antibodies directed against CD11 or CD18 (63). Heterozygous siblings or parents show about half-normal amounts of the surface glycoproteins. Similarly, parents of affected offspring with IL-12 receptor  $\beta$ 1 deficiency reveal half-normal amounts of cell-surface receptor expression, indicating the possibility of carrier detection by flow cytometry. Heterozygotes in actin dysfunction syndrome show retarded actin polymerization as determined by flow cytometric analysis of NBD-phalloidin staining (141). Heterozygotes which carry a defective lysosomal enzyme gene encoding for a macrophage storage disease can be detected by measuring enzyme activity in cultured fibroblasts and leukocytes. It is likely that future studies will develop additional simple and rapid ways to detect the carrier states of other granulocyte function disorders. As the specific genes for these disorders are pinpointed, identification of the carrier state can be carried out using specific probes, sequence analysis, or PCR techniques, followed by gene polymorphism determination.

**82.5.5.2 Secondary Prevention.** Recent advances in molecular, biochemical, hematologic, and obstetric techniques have made early diagnosis and intervention for some of the congenital phagocyte disorders available. Chorionic villus sampling at 9–10 weeks of gestational age and fetal blood sampling at 16–20 weeks of gestational age, as well as sampling of peripheral blood from suspected patients and their family members, provide tissue for chromosome analysis, RFLP, single-stranded conformational polymorphism followed by direct sequencing, biochemical analysis, gene product measurement, and cell function assays (261–263,265,266). The gene coding for CGD is not critical for the development of the granulocytes, so that nonrandom X-inactivation does not occur in affected granulocytes. Employing the nitroblue tetrazolium dye reduction test preferably, or dihydrorhodamine fluorescence, CGD can be diagnosed prenatally at approximately 16–20 weeks' gestation (264).

Some individuals with the X-linked form of CGD arising from gene deletion may be detected prenatally using a DNA probe (10,262,267). The specific gene responsible for this disorder has also been determined, and prenatal diagnosis for the different genotypes of CGD has been made possible (261,267,268). Granulocytes as well as other granule-containing cells from patients with CHS have giant lysosomal granules, the characteristic morphology of which can be used to detect the syndrome in fetal cord blood samples at 18–20 weeks of gestational age. Similarly, fetal cord blood sampling may also provide the diagnosis of disease or carrier detection in LAD by measurement of the gene product (CD18 complex) in midtrimester. Leukocytes from cord blood or fibroblasts from amniotic cells can be cultured for detecting metabolic storage diseases by measuring suspected lysosomal enzyme activity. PCR (269) permits a prenatal diagnosis of  $\alpha$ 1-antitrypsin deficiency using fewer than 100 amniocytes or from small samples of fetal blood (270). An accurate prenatal diagnosis may be made in 1 day with this technique (267,268). Prenatally detected phagocyte function disorders may be managed by therapeutic abortion. Gene therapy may become available even for intrauterine therapy for fetuses with CGD or other genetic leukocyte function disorders. Recently, RD114 envelope pseudotyped vectors capable of transducing more than 95% of CD34+ stem cells have been developed (271).

**82.5.5.3 Management of Disease Complications (Tertiary Support).** Patients with phagocyte function disorders should receive physical, psychosocial, and rehabilitative support. Physicians should coordinate the support systems to assist in preventing infections, the development of physical dysfunction, and psychosocial problems. As discussed, BMT may occasionally be curative. Alternatively, antibiotic prophylaxis, chest physiotherapy, and surgical drainage may reduce sequelae. Regular visits to a dentist familiar with the problems suffered by patients with phagocyte function disorders are essential, especially for those with LAD. Patients with phagocyte abnormalities who suffer from recurrent infections since infancy usually develop psychological problems secondary to physical changes (skin scarring, coarse facies, hearing loss, dental decay, and/or pulmonary dysfunction), loss of schooling, or the recurring need for hospitalization or intravenous antimicrobial therapy. Caring for patients with phagocyte function disorders requires teamwork involving family, medical, and social support. The exciting prospect for these patients and their physicians is the future possibility of early diagnosis and genetic therapy to correct these disorders.

### Biographies

**Harry R. Hill** Dr Hill is a Professor of Pathology, Pediatrics and Internal Medicine. He serves as the Head of the Division of Clinical Immunology at the University of Utah School of Medicine. Dr Hill is a Senior Vice President at ARUP, Inc., and the Executive Director of the ARUP Institute for Clinical and Experimental Pathology, which is the research arm of ARUP Laboratories with 90 scientists and 55 medical directors. After receiving his MD from Baylor School of Medicine, he received pediatric and immunology training at the University of Washington. Dr Hill then trained in immunology, infectious diseases, and clinical laboratory medicine at the University of Minnesota. He was also an Epidemic Intelligence Service officer with the CDC at the Streptococcal Disease Laboratory in Fort Collins, Colorado for 2 years. He was NIH-funded for work on group B, and more recently group A streptococcal disease for 30 years and has over 389 peer-reviewed articles, textbook chapters, and reviews. His clinical work involves seeing adult and pediatric patients with primary immunodeficiencies. Current research efforts are directed at the discovery of new molecular causes of primary immune deficiencies and the development of rapid diagnostic tests for these disorders.

**Kuender D. Young** Dr Kuender D. Yang from Taiwan has been devoted to the study of infections and immunity since 1980's. He did his doctoral dissertation on fibronectin-mediated signal transduction in phagocyte defense against bacterial infections (Yang et al., *J. Infect. Dis.* 1990, 161, 236–241; *J. Cell Physiol.* 1994, 158, 347–353) with Professor Harry R. Hill in the Departments of Pediatrics and Pathology at the University of Utah School of Medicine. He also did fellowship work in Molecular Pharmacology at the Dana Farber Cancer Institute, Harvard Medical School (Mentors: Don Kufe, MD and Richard M. Stone, MD; 1991–1992), and published a study on retinoic acid induction of PKC $\beta$  for monocytic differentiation in Blood (Yang et al., *Blood* 1994, 83, 490–496). Dr Yang was promoted to a full professor in 1997 at Tri-service General Hospital, Taipei, Taiwan. Since 1997, Dr Yang has joined Chang Gung University and been studying the immunopathogenesis of common emerging infections, including enterovirus 71, SARS, dengue hemorrhagic fever and novel swine H1N1 influenza, in Taiwan. He has published over 200 refereed articles. He has recently focused on studying genomic and epigenomic mechanisms of dengue hemorrhagic fever and perinatal programming of adult diseases, particularly allergic diseases, funded by the National Science Council, National Health Research Institute and National Genomic Research Program of Taiwan.

**Attila Kumánovics** Attila Kumánovics is a molecular genetic pathology fellow at the University of Utah. He received his MD from the University of Pécs School of Medicine in Pécs, Hungary and his residency training in clinical pathology and fellowship training in diagnostic immunology at the University of Utah School of Medicine in Salt Lake City, Utah, USA. He did research at the Howard Hughes Medical Institute and University of Texas Southwestern School of Medicine in Dallas, Texas, USA, and at the University of Utah School of Medicine in Salt Lake City, Utah, USA. His clinical and research interest is in the genetics of the immune system. He first studied the genes and genomics of the major histocompatibility complex and now concentrates on primary (genetic) immunodeficiencies.

### 83.1 INTRODUCTION

The pituitary gland is composed of two embryologically, morphologically, and functionally distinct units, the anterior pituitary (adenohypophysis) and the posterior pituitary (neurohypophysis). Disease processes usually involve only one of these units unless both are affected because of their anatomic proximity or because of hypothalamic involvement. Thus, disorders of anterior and posterior pituitary functions are discussed separately in this chapter.

### 83.2 ANTERIOR PITUITARY

#### 83.2.1 Normal Pituitary Development and Function

The anterior pituitary is derived from an epithelial invagination of the roof of the posterior pharynx, Rathke's pouch. This mass of cells migrates upward toward the base of the brain to meet an outpouching of the third ventricle, the future posterior pituitary. The pituitary gland comes to lie in a bony cavity of the sphenoid bone known as the sella turcica. It is separated from the brain superiorly by the diaphragma sella, an extension of the dura mater. The pituitary stalk, composed primarily of neurohypophyseal tissue surrounded by nerves and blood vessels, passes through the diaphragma sella, connecting the gland with the hypothalamus. This intimate vascular connection between the hypothalamus and the pituitary allows sensitive hypothalamic control of pituitary function.

The anterior pituitary gland contains a number of distinct cell types responsible for the secretion of the pituitary hormones: growth hormone (GH), thyroid stimulating hormone (TSH), adrenocorticotrophic hormone (ACTH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), prolactin (PRL), and melanocyte-stimulating hormone (MSH). The secretion of each of these is under the direct control of the hypothalamus. This hypothalamic control of pituitary secretion is mediated by a variety of hypothalamic-releasing hormones, which stimulate the secretion of the specific pituitary hormones (e.g. thyrotropin releasing hormone (TRH) stimulates TSH secretion), and hypothalamic inhibitory hormones, which inhibit the secretion of specific pituitary hormones (e.g. somatostatin (SST) inhibits GH secretion). The interplay between the specific releasing and the inhibitory hormones directly controls the secretion of each of the pituitary hormones. In turn, the secretion of the hypothalamic inhibitory and releasing hormones by the hypothalamus is modulated by a variety of humoral and central nervous system (CNS) factors. The pituitary hormones, once released into the plasma, exert their effects on their targets, either a specific endocrine gland (e.g. thyroid) or a variety of end organs. Because of the complexity of this hypothalamopituitary axis, a variety of pathogenetic mechanisms can operate at each level of the system, resulting in a widely heterogeneous group of disorders with similar symptoms of pituitary insufficiency (Table 83-1).

Isolated deficiencies of TSH, ACTH, LH, and FSH have been reported in Table 83-1. As the clinical symptoms produced are the result of the target organ hormone deficiency (e.g. hypothyroidism, hypoadrenalism, or

**TABLE 83-1 Selected Genetic Disorders that May Affect Pituitary Development or Function<sup>a</sup>**

Name of Disorder	OMIM	Mode	Locus	Gene/OMIM	Endocrine Features
Adrenal hypoplasia, congenital	300200	XL	Xp21.3-p21.2	NROB1 aka DAX1/300473	Primary adrenal insufficiency, XY sex reversal, hypogonadotropic hypogonadism
Adrenocorticotrophic hormone (ACTH) deficiency, isolated	201400	AR	1q23-q24	TBX19/604614	Central adrenal insufficiency
Alopecia, neurologic defects, and endocrinopathy syndrome	612079	AR	7q32.1	RBM28/612074	Pituitary hypoplasia, hypogonadotropic hypogonadism, central adrenal insufficiency

<sup>a</sup>Genetic disorders affecting genes in the growth hormone pathway, causing combined pituitary hormone deficiency, or associated with endocrine neoplasia are treated separately (Tables 83-2, 83-3, and 83-5 respectively).

hypogonadism), they are discussed in the corresponding endocrine organ chapters (Chapters 84, 87, and 88). This chapter focuses primarily on developmental disorders of the pituitary and disorders of the GH axis.

**83.2.1.1 The Role of Transcription Factors in Pituitary Development.** A complex cascade of transcription factors guides the development of the anterior and posterior pituitary. Transcription factor signaling in both the developing oral ectoderm (eventually to become Rathke’s pouch) and the ventral diencephalon is important for initiation of pituitary development as well as migration of the nascent anterior pituitary to its final location. Important factors in early pituitary development include PITX1/2 (OMIM 602149/601542), HESX1 (OMIM 601802), SHH (OMIM 600725), and LHX3/4 (OMIM 600577/602146), while genes such as *PROP1* (OMIM 601538) and *POU1F1* (also called PIT1, OMIM 173110) play an important role in the differentiation of anterior pituitary hormone-secreting cells. In general, disruptions of genes involved in early pituitary development result in more severe defects and often brain anomalies (e.g. holoprosencephaly due to SHH mutations, Table 83-1), while defects in genes involved in later aspects of pituitary development lead to varying combinations of pituitary hormone deficiencies (Table 83-2). For an excellent review of transcription factor signaling in pituitary development, see (1,2).

Two key transcription factors in the development and function of the anterior pituitary are *PROP1* and *POU1F1*. *PROP1* appears early in anterior pituitary development and is important for differentiation of anterior pituitary cell lineages. *PROP1* forms a complex with  $\beta$ -catenin and this complex both represses *HESX1* expression and activates *POU1F1* expression, leading to progression of cellular determination (1).

*POU1F1* is a member of the POU family of transcription factors that regulate mammalian development (Figure 83-1). The POU family is so named because the first three members identified were *POU1F1* and

*OCT1* of mammals and *Unc-86* of *Caenorhabditis elegans*. *POU1F1* contains two protein domains, termed POU-specific and POU-homeo, which are both necessary for high-affinity DNA binding on genes encoding GH and PRL. *POU1F1* is also important for regulation of the genes encoding PRL and the TSH $\beta$  subunit by TRH and cyclic AMP.

**83.2.1.2 The Growth Hormone Gene.** GH is a multifunctional hormone, produced in the pituitary, which promotes postnatal growth of skeletal and soft tissues through a variety of effects (Figure 83-1). Controversy remains about the contribution of direct and indirect actions of GH. GH receptors (GHRs) have been documented in a number of cell types. A major portion of the effects of GH are mediated through the actions of GH-dependent insulin-like growth factor 1 (IGF1, also called somatomedin C). IGF1 is produced in many tissues, primarily the liver, and acts through its own receptor (IGF1R, OMIM 147370) to enhance the proliferation and maturation of many tissues, including bone, cartilage, and skeletal muscle. In addition to promoting tissue growth, GH has also been shown to exert a variety of other biological effects, including lactogenic, diabetogenic, lipolytic, and protein-anabolic effects, as well as sodium/water retention.

At the cellular level, a single GH molecule binds two GHR molecules, causing them to dimerize. Dimerization of the two GH-bound GHR molecules leads to signal transduction, through the JAK-STAT pathway. It has been suggested that the diverse effects of GH may be mediated by a single type of GHR molecule, which can possess different cytoplasmic domains and/or phosphorylation sites in different tissues. When activated by JAK2, these differing cytoplasmic domains can lead to distinct phosphorylation pathways, one for growth effects and others for various metabolic effects.

The gene encoding GH (GH1, OMIM 139250) and those genes encoding chorionic somatomammotropin hormones (CSH1/2, OMIM 150200/118820) reside in a 50,000 base-pair (50kb) gene cluster on human

chromosome 17. The GH2 gene (OMIM 139240) also resides in this cluster and encodes a protein (GH2) that is expressed in the placenta rather than in the pituitary, and differs from the primary sequence of GH by 13 amino acids. The CSH1/2 genes encode proteins of identical sequences, whereas the CSH pseudogene (CSHP1) encodes a protein differing by 13 amino acids and contains a mutation that should alter its pattern of messenger RNA (mRNA) splicing and thus the primary sequence of the resulting protein. The extensive homology (92–98%) between the immediate flanking, intervening, and coding sequences of these five genes suggests that this multigene family arose through a series of gene duplication events. These duplications are thought to have arisen from successive unequal recombinations between Alu family repeats. This method of gene amplification is analogous to the Alu–Alu recombinations that cause deletions of the human  $\beta$ -globin and low-density lipoprotein receptor genes.

Expression of the GH1 gene is controlled by *cis* and *trans* factors. The former include the CAT and TATA promoter components located, respectively, 85 and 30 bp upstream from the GH1 gene's origin of transcription. In addition, there are *cis* sequences that bind the POU1F1 transacting factor. Thus, POU1F1 binds to and activates the promoters of the GH1 and PRL genes, and also affects differentiation of thyrotropes.

**83.2.1.3 Disorders of Pituitary Function.** Hereditary disorders of both pituitary hypofunction and hyperfunction have been described (Tables 83-1–83-3, 83-5).

Similar to genetic disorders of the other endocrine glands, diseases involving hormone deficiency states are much more frequent and better delineated than hereditary forms of hormone excess. Pituitary deficiency disorders may involve a single tropic hormone (isolated or monotropic deficiency) or a combined pituitary hormone deficiency (CPHD, deficiency of two or more pituitary hormones) and may result from disturbances in any part of the hypothalamohypophyseal-target organ complex (Tables 83-1-83-3). Theoretically, a syndrome of pituitary hormonal insufficiency might result from developmental, degenerative, or receptor lesions of the hypothalamus, deficiencies of the hypothalamic-releasing hormones or their receptors, developmental or degenerative lesions of the pituitary gland, deficiencies or structural abnormalities of the pituitary hormones, or defects in target organ responsiveness to hormonal action. Each of these mechanisms has now been described in patients with pituitary insufficiency, resulting in the marked genetic heterogeneity that has been observed in pituitary disorders (3).

### 83.2.2 Developmental Anomalies and Syndromes

### 83.2.2.2.1 Congenital Absence or Hypoplasia of the Pituitary.

Complete absence of the anterior pituitary gland results in severe neonatal adrenal insufficiency, hypothyroidism, and hypoglycemia and, if untreated, usually results in neonatal death. This syndrome probably goes unrecognized in most cases, unless the adrenal insufficiency is diagnosed early and pituitary function is then studied, or postmortem examination includes a detailed examination of the pituitary fossa. The sella turcica is usually small and no trace of anterior pituitary tissue is found at autopsy. Posterior pituitary tissue may be present or absent. There is atrophy of the adrenals with absence of the fetal zone, presumably secondary to ACTH deficiency.

Clinical features include early lethargy, cyanosis, convulsions, circulatory collapse, and hypoglycemia. Neonatal jaundice has been documented and may occur with most forms of neonatal hypopituitarism. The thyroid and gonads may be hypoplastic and the penis is usually small. Survival past the neonatal period will result in severe dwarfism, hypogonadism, and cretinism, but early total hormone replacement therapy should result in complete phenotypic reversal. Thus, baseline endocrine tests should be performed immediately followed by magnetic resonance imaging (MRI) of the brain in neonates with hypogonadism and unexplained hypoglycemia, so that the irreversible neurological and developmental consequences of panhypopituitarism can be prevented (4).

Sobrier and colleagues described a consanguineous family in which two siblings displayed a complete absence of the anterior pituitary revealed by a deficit in

all anterior pituitary hormones (5). One patient, who also had retinal coloboma, carried a HESX1 defect in the homozygous state. HESX1 mutations in humans have been associated with various pituitary hormone deficiencies usually combined with optic nerve anomalies (see Sections 83.2.2.6 and 83.2.3).

A syndrome of congenital hypopituitarism with severe hypoglycemia and microphallus, which resembles congenital absence of the pituitary clinically, has been described. Plasma PRL was normal or elevated and there was a TSH rise following TRH administration, indicative of a hypothalamic defect. All these cases were sporadic. Hypoplasia or ectopia of the pituitary gland has also been described with pituitary insufficiency. It is impossible to state whether these latter disorders are simply less complete forms of pituitary agenesis or secondary to distinct pathogenetic mechanisms.

Yagi et al. described three brothers with congenital CPHD and central diabetes insipidus (DI). MRI indicated absence of the pituitary stalk, severe hypoplasia of the anterior pituitary, and an absent or ectopic posterior pituitary. Also, Shashi and colleagues described two brothers who had features of orofaciocigital (OFD) syndrome types II and VI and Pallister–Hall syndrome (PHS), both of whom had congenital absence of the pituitary gland, and suggested that this represented yet another pleiotropic effect of the OFD syndrome.

**TABLE 83-5 Selected Neoplastic Syndromes Affecting the Pituitary Gland**

Online Mendelian Inheritance in Man, OMIM (TM). McKusick–Nathans Institute of Genetic Medicine, Johns Hopkins University (Baltimore, MD) and National Center for Biotechnology Information, National Library of Medicine (Bethesda, MD), Accessed October 2010–March 2011. World Wide Web URL: <http://www.ncbi.nlm.nih.gov/omim/>.

Ferrier and Stone described two sisters who had severe growth failure, hypoglycemia, and mental retardation, and who manifested evidence of relative GH, TSH, and ACTH deficiency (OMIM 262700; Table 83-2). These individuals differed from the usual form of hereditary CPHD in that both had a very small sella turcica located in a morphologically abnormal sphenoid bone. The authors postulated that the association of CPHD, mental retardation, and abnormal sella turcica may represent a distinct syndrome inherited as an autosomal recessive trait. Two sisters with a similar syndrome of CPHD with a poorly developed sella turcica were later described by Sipponen and colleagues. On autopsy, no pituitary gland could be found in one child and only a rudimentary, partly ectopic pituitary in the other. Thus, there are some questions as to whether this represents a distinct syndrome or is simply a less severe form of congenital absence of the pituitary.

Hypoplasia of the pituitary with ectopic posterior pituitary has also been reported as part of a constellation of alopecia, neurological defects, and endocrinopathy (ANE syndrome), with central hypogonadism and central hypothyroidism (6). The patients were found to have a homozygous mutation of *RBM28*, which encodes an 85 kDa protein that forms part of snRNP complexes. Rough endoplasmic reticulum (ER) structure and ribosome density were both abnormal in these patients, although the exact mechanism by which deficiency of this protein causes the ANE syndrome is unclear.

**83.2.2.2 Anencephaly.** Anencephaly is associated with the complete absence of a normal hypothalamus, absence or severe hypoplasia of the posterior pituitary, and variable degrees of anterior pituitary hypoplasia (OMIM 206500, 301410; Table 83-1). These infants have hypoplastic adrenals and often die from adrenal insufficiency. Plasma GH levels have been found to vary from low normal to deficient in anencephalic infants. The intravenous insulin tolerance test has failed to evoke elevations in plasma GH in anencephalic infants. Administration of lysine–vasopressin caused active GH release, however, and there was a large increase in serum TRH. Thus, the anterior pituitary appears to be capable of releasing GH

and TSH when directly stimulated, but anterior pituitary function mediated by hypothalamic-releasing hormones appears to be totally deficient. These endocrinologic data are supported by histologic observation of TSH-, FSH/LH-, and GH-secreting cells in the pituitaries of these infants.

**83.2.2.3 Holoprosencephaly.** The holoprosencephalies form a spectrum of developmental anomalies associated with impaired midline cleavage of the embryonic forebrain, aplasia of the olfactory bulbs and tracts, and midline dysplasia of the face, ranging from cyclopia to cleft lip and palate with hypotelorism (OMIM 236100, 157170; Table 83-1). Anomalies of the pituitary gland have been described in all forms of holoprosencephaly, ranging from malformation of the gland to its complete absence. In individuals with absence of the pituitary, the adrenals are also hypoplastic and there may or may not be thyroid hypoplasia as well. Hypoplastic or aplastic pancreas, testes, and ovaries have also been described. ACTH deficiency and neurohypophyseal DI (NDI) have been documented. All degrees of insufficiency may occur in the holoprosencephalies, and the degree of pituitary dysfunction appears to be unrelated to the severity of the facial deformity. The pituitary insufficiency is presumably secondary to a developmental anomaly of the hypothalamus. The holoprosencephalies are a genetically heterogeneous group of disorders associated with 7q, trisomy 13, deletion of the short arm of chromosome 18, simple autosomal dominant or recessive inheritance, and a variety of other chromosomal anomalies (see Chapter 115). Mutations have been described in a number of genes, including *SHH*, *ZIC2*, *SIX3*, and *TGIF* (7). Twelve loci have been defined on 11 chromosomes (8).

**83.2.2.4 Transsphenoidal Encephalocele.** A number of cases of transsphenoidal encephalocele associated with variable degrees of hypothalamopituitary dysfunction have been reported. In transsphenoidal encephalocele, a defect exists in the sphenoid bone and the encephalocele usually extends into the epipharynx. Associated features include an epipharyngeal or nasopharyngeal mass, hypotelorism, midfacial or midline craniocerebral anomalies, and optic nerve abnormalities. The facial appearance is

characterized by a broad nasal root. Hormonal deficiencies have been reported in these patients, including GH, TSH, ACTH, LH, FSH, PRL, and ADH deficiencies. In individual patients, pituitary function has ranged from normal, to an isolated hormone deficiency such as isolated GH deficiency (IGHD), to CPHD. In one autopsied proband, degeneration of the hypothalamus and agenesis of the supraoptic nuclei were found. Duplication of the pituitary and agenesis of the corpus callosum have also been described. Double pituitary glands have been described with a variety of craniofacial malformations. Diagnosis of this syndrome is important, as iatrogenic hypopituitarism has been described following extirpation of a nasopharyngeal mass containing anterior and posterior pituitary tissue in a case whose sphenoidal defect was not recognized preoperatively. Although the majority of cases of transsphenoidal encephalocele are sporadic, two sibs with transsphenoidal pituitary herniation, midfacial anomalies, and CPHD, who were the offspring of a consanguineous mating, have been described, suggestive of autosomal recessive inheritance in some families.

**83.2.2.5 Empty Sella Syndrome.** Primary empty sella is caused by a defect in the diaphragma sellae, with extension of the subarachnoid space into the sella turcica, resulting in a diffusely enlarged sella. Although patients typically have normal pituitary function, it can be familial and associated with other anomalies, as well as short stature and pituitary deficiency. Yokoyama and colleagues found a duplication of the q13.3–q21.2 region of the X chromosome in patients with GH deficiency and empty sella syndrome.

**83.2.2.6 Septo-Optic Dysplasia.** Septo-optic dysplasia (SOD, OMIM 182230) is a rare malformation of the anterior midline structures of the brain (Table 83-1). The classic triad includes optic nerve hypoplasia, midline brain defects (most commonly absent or cavum septum pellucidum or agenesis of the corpus callosum), and hypopituitarism, sometimes with hypoplasia of the anterior pituitary and/or ectopic posterior pituitary. Severely affected neonates may present with signs of hypopituitarism including hypoglycemia and prolonged jaundice; patients may also have defective vision, behavioral delay, hypotonia, and seizures. In mildly affected cases, the child may present with proportionate short stature and pendular nystagmus, with or without amblyopia. Ophthalmologic examination reveals bilateral hypoplasia of the optic nerves, with small optic discs and irregular field defects. Absence of the septum pellucidum can be diagnosed prenatally by ultrasound examination (9). Any or all of the three major defects (brain, optic tract, pituitary) may be present. Morishima and Aranoff concluded that only 30% of fully evaluated patients had evidence of all three components. Intelligence may be normal or mildly to moderately affected. The pituitary insufficiency, which may vary from IGHD to CPHD, is probably secondary to a diencephalic malformation resulting in deficiency of one or more of the hypothalamic-releasing hormones. Sexual precocity has been reported, as

has hypersecretion of other pituitary hormones, including GH, ACTH, and PRL. Autopsy has shown absence of the posterior pituitary and diffuse lesions of the hypothalamus, optic nerves, corpus callosum, and olfactory tract, as well as defects in the cerebral cortex. A variety of other anomalies, including hand and facial defects, have occasionally been described. This syndrome should be considered in any child with hypopituitarism and nystagmus or abnormalities of the optic disc. Almost all of the cases described to date with SOD and growth retardation have been sporadic, with no evidence of ocular anomalies or hypopituitarism in their parents or sibs. Dattani and colleagues (3) demonstrated homozygosity for a missense mutation in the HESX1 gene in a brother and a sister with agenesis of the corpus callosum and panhypopituitarism. Subsequently, other patients with SOD and pituitary defects have been found to have HESX1 mutations, although it appears to be a relatively rare cause (fewer than 1% of patients with SOD and hypopituitarism) (10). HESX1 is described further in Section 83.2.3.

SOX2 and SOX3 are HMG-box containing transcription factors expressed in the developing brain. Duplications of SOX3 (OMIM 313430) have been associated with X-linked hypopituitarism and mental retardation; some of these patients have been reported to have abnormalities of the corpus callosum but not the optic tract. On the other hand, patients with SOX2 (OMIM 184429) mutations may have severe optic manifestations including microphthalmia or even anophthalmia in association with hypopituitarism (11,12). Birrell and colleagues have reported two patients with Borjeson–Forssman–Lehmann syndrome and CPHD who also had optic nerve hypoplasia, which may represent a variant of SOD. The patients had a missense mutation in the PHF6 gene, which caused an early stop codon (K8X) (13).

**83.2.2.7 Cleft Lip and Palate.** Midline cleft lip and palate can be associated with GH deficiency, DI, holoprosencephaly, and optic nerve hypoplasia with absence of the septum pellucidum (14). Functional pituitary insufficiency has been described in a number of individuals with cleft lip and palate who did not have other facial or neurologic abnormalities. Pituitary insufficiency may vary from complete CPHD associated with congenital aplasia of the pituitary to IGHD. Rudman and colleagues studied 200 children with isolated clefts and found 4% with GH deficiency (40 times higher than the frequency in children without clefts). Short children with cleft lip and palate and growth retardation should thus be subjected to a complete pituitary evaluation. One can speculate that this disorder is simply the mild end of the spectrum of the holoprosencephaly–SOD range of hypothalamic anomalies associated with pituitary insufficiency (also see Section 83.2.2.13). Thus, any individual with cleft lip and/or palate and hypopituitarism deserves brain imaging.

**83.2.2.8 Solitary Maxillary Central Incisor.** Solitary maxillary central incisor may occur as an isolated defect

or as a milder manifestation of hereditary holoprosencephaly. In one series of seven patients with a single maxillary central incisor in both deciduous and permanent dentition and short stature (OMIM 147250, [Table 83-1](#)), five had documented GH deficiency. Two who were treated with GH had a good growth response. No other pituitary hormone deficiencies were found. The patients had normal facies or only mild midline facial anomalies, and there was no evidence of hypothalamic or optic defects.

A number of other cases of single central maxillary incisor in association with short stature have been reported. Boudaille et al. discovered hypopituitarism associated with mental retardation, dysmorphic features, and solitary maxillary incisor. A deletion of 18p has been reported in several cases. This observation suggests that the cause of the pituitary insufficiency in other cases of 18p- and pituitary dwarfism may be secondary to midline brain and hypothalamic defects.

Single central maxillary incisor has also been described in association with precocious puberty and a hypothalamic hamartoma, and in a dominant ectodermal dysplasia syndrome consisting of mild short stature, sparse scalp hair, skin pigmentation, and “hypoplastic” thumbs. Thus, this dental defect should alert one to the possibility of midline CNS defects and pituitary deficiency. Hall and colleagues described 21 cases of solitary median maxillary central incisor syndrome, pointing out that this syndrome is a possible predictor of holoprosencephalies of varying degrees in the proband, and related family members. A missense mutation in the sonic hedgehog (SHH) gene was found in eight members of a single family without holoprosencephaly, three of whom had a single central maxillary incisor ([15](#)). An SHH missense mutation was also described in a holoprosencephaly family in which the mother has a single central maxillary incisor and mild hypotelorism ([16](#)).

**83.2.2.9 Pallister–Hall Syndrome.** Hall and colleagues described a neonatally lethal malformation syndrome consisting of hypothalamic hamartoblastoma, hypopituitarism, postaxial polydactyly, and imperforate anus (OMIM 146510; [Table 83-1](#)). Variable features include laryngeal cleft, abnormal lung lobulation, renal agenesis and/or renal dysplasia, short fourth metacarpals, nail dysplasia, multiple buccal frenula, hypoadrenalism, microphallus, congenital heart defects, and intrauterine growth retardation. The hypothalamic tumor was apparent on the inferior surface of the cerebrum and extended from the optic chiasma to the interpeduncular fossa. The tumor replaced the hypothalamus and other nuclei that originate in the embryonic hypothalamic plate. It was composed principally of cells resembling primitive undifferentiated germinal cells. The olfactory bulbs and tracts were short and thick, suggesting a relationship to the holoprosencephaly syndromes. An anterior pituitary gland was absent in all cases and the posterior pituitary was absent in the majority. The associated adrenal

hypoplasia, small thyroid, and microphallus are presumably secondary to pituitary insufficiency.

Most babies with PHS die in infancy probably as a result of secondary adrenal insufficiency. Graham and colleagues reported the survival of one child who was promptly treated for pituitary insufficiency in infancy and then had a hypothalamic tumor surgically resected at 1 year of age. Thus, medical and surgical treatment of this syndrome is possible. Prenatal diagnosis may also be accomplished by measurement of decreased levels of maternal estriol, prenatal ultrasonography for the fetal adrenal, renal, or brain abnormalities, and measurement of amniotic fluid disaccharides, which would be decreased with an imperforate anus. Feuillan et al. studied hypothalamic function in 14 patients with PHS, and found that 6/7 (86%) children and 6/8 (75%) adults had decreased spontaneous GH secretion; most of the patients were not assessed with formal GH stimulation tests, and some of the adult patients had normal stature, suggesting that they may not have had true GH deficiency. Only one patient had an abnormal pituitary–gonadal axis (manifested as precocious puberty) and none had adrenal or thyroid dysfunction ([17](#)).

Familial cases of PHS exhibit autosomal dominant inheritance; sporadic cases also occur. This disorder is not always lethal in infancy, as a father of two affected siblings had mild manifestations of the disease, and two other unrelated patients with the full-blown syndrome were reported at 2 and 17 years of age. Overlap of this syndrome with Smith–Lemli–Opitz syndrome type II, OFD syndrome type VI, the holoprosencephaly–polydactyly syndrome, and McKusick–Kaufman syndrome have been suggested. However, molecular studies have disproved these comparisons. Kang et al. have shown that Greig cephalopolysyndactyly syndrome (GCPS) maps to the same region of chromosome 7p as does PHS. They reported two PHS families with frameshift mutations in *GLI3*, whereas haploinsufficiency of the *GLI3* gene has been noted with GCPS. A boy with PHS, with short stature, and GH neurosecretory dysfunction was found to have deficient spontaneous GH secretion despite a normal response to pharmacologic stimulation. The patient responded positively to long-term GH treatment ([18](#)). Johnston and associates screened 46 patients with PHS and 89 patients with GCPS for *GLI3* mutations. They detected 47 pathologic mutations (among 60 probands), and when these mutations were combined with previously published mutations, 2 genotype–phenotype correlations were evident. GCPS was caused by many types of alterations, including translocations, large deletions, exonic deletions and duplications, small in-frame deletions, and missense, frameshift/nonsense, and splicing mutations. In contrast, PHS was caused only by frameshift/nonsense and splicing mutations. Among the frameshift/nonsense mutations, they found a clear genotype–phenotype correlation. Mutations in the first third of the gene (from open reading frame nucleotides 1–1997) caused GCPS, and

mutations in the second third of the gene (from nucleotides 1998–3481) caused primarily PHS. Surprisingly, there were 12 mutations in patients with GCPS in the 3' third of the gene (after open reading frame nucleotide 3481), and no patients with PHS had mutations in this region (19). Thus, there is a clear genotype–phenotype correlation for GLI3 mutations.

**83.2.2.10 CHARGE syndrome.** CHARGE is an acronym that was coined to describe a nonrandom association of anomalies: Coloboma of the eye; Heart disease; choanal Atresia of the choanae; Retarded growth, development, and/or CNS anomalies; Genital hypoplasia; and Ear anomalies or deafness (OMIM 214800; Table 83-1). Other prominent features include facial palsy, micrognathia, cleft palate, swallowing difficulties, tracheoesophageal fistula, and a “wedge-shaped” audiogram.

Hypogonadotropic hypogonadism is a frequent feature, and in boys may manifest as cryptorchidism, microphallus, and/or hypospadias. Girls typically will not have symptoms of gonadotropin deficiency until later in childhood when they may present with delayed puberty. Although growth retardation also occurs frequently in patients with CHARGE association, GH is usually normal on testing. However, August et al. documented both GH and gonadotropin deficiencies in a girl with the association, who also had a delayed peak TSH response to TRH. Davenport and colleagues found GH borderline responses to arginine and insulin in one patient. Arhinencephaly and holoprosencephaly have been reported suggesting a hypothalamic cause for the pituitary deficiencies. Zuppinger and associates described an unusual patient with coloboma of the right choroid and optic nerve, cleft lip, GH deficiency, DI, and central hypothyroidism. None of the other features of the CHARGE association were present. Finally, James et al. (20) have reported a patient with CHARGE association accompanied by both hypogonadotropic hypogonadism and central adrenal insufficiency.

Visser and colleagues reported a 2.3Mb de novo overlapping microdeletion on chromosome 8q12 in two individuals with CHARGE syndrome (21). Sequence analysis of genes located in this region detected mutations in CHD7 in 10/17 (59%) of individuals with CHARGE syndrome who did not have microdeletions, thus accounting for the disease in most affected persons. CHD7 (OMIM 608892) is a DNA-binding protein involved in remodeling of chromatin and regulation of gene expression. Although dominant inheritance occurs, most mutations are de novo. The phenotype of CHARGE syndrome due to CHD7 mutations is highly variable, possibly due to somatic and/or germline mosaicism possibly with other modifying factors (22). An individual with CHARGE syndrome with an apparently balanced chromosome 6 and 8 translocation has been reported. Martin et al. reported a patient with CHARGE syndrome and a balanced translocation between chromosomes 2 and 7 (23). Lalani et al. performed further characterization of

this translocation and identified a breakpoint at 7q21.11. They identified the gene SEMA3E within 200kb of the breakpoint, and confirmed a mutation in SEMA3E in a second unrelated patient with CHARGE syndrome. SEMA3E encodes semaphorin 3E, one of a group of proteins involved in processes such as cell migration, axonal guidance, and heart development. Animal homologs of SEMA3E are expressed in the nasal placode, otic placode, and semicircular ducts, consistent with tissues involved in CHARGE (24).

**83.2.2.11 Chromosomal Syndromes.** Growth hormone deficiency has been described with deletions of chromosomes 18q (OMIM 601808), 18p (OMIM 146390), and 20p (Table 83-1). In addition, deletions of 17q (the GH gene cluster region) have been documented in IGHD type IA (see later discussion). Because the gene for GHRH has been mapped to 20p, the GH deficiency in 20p deletion could result from either the deletion of the *GHRH* gene or a developmental anomaly of the hypothalamus. The deletion in one such 20p deletion patient, however, did not include the *GHRH* locus. A patient with 18p deletion has been reported with hypopituitarism and solitary central maxillary incisor, suggesting that the pituitary insufficiency in 18p deletion may be due to a structural malformation of the hypothalamus. GH deficiency has been rarely associated with 47,XXY; 49,XXXXY; and ring 5. A boy with moderate intellectual disability associated with distinctive hand malformations (hypoplastic and angel-shaped middle phalanges) was found to have GH deficiency associated with mosaic deletion of 13q31.1–13q32.3 (25).

**83.2.2.12 Borjeson–Forssman–Lehmann Syndrome.** The X-linked Borjeson–Forssman–Lehmann syndrome is characterized by short stature, hypogonadism, hypotonia, severe mental deficiency, and coarse facial appearance with a prominent brow ridge and large ears in affected males (OMIM 301900; Table 83-1). Carrier females show a wide range of expression. A variety of other ocular and skeletal anomalies may also occur. Normal stimulated GH secretion in one patient has been reported. Robinson et al. documented markedly deficient GH responses to arginine and L-dopa, as well as low IGF1 levels in a severely affected male and both of his mildly affected twin sisters. The growth deceleration in this syndrome, however, may not begin until 8–10 years of age, and therefore the pituitary deficiency may be progressive. This syndrome was initially mapped to Xq26–q27; the gene for this disorder, PHF6, has now been identified (26). Birrell and colleagues (13) have reported a case of a patient with BFLS and deficiency of GH, ACTH, TSH, and gonadotropins associated with optic nerve hypoplasia, who had a premature stop codon in PHF6. Assessment of skewing of X-inactivation in suspected female carriers may identify those with PHF6 mutations (27).

**83.2.2.13 Ectrodactyly–Ectodermal Dysplasia–Clefting Syndrome.** One patient with the ectrodactyly–ectodermal dysplasia–clefting syndrome (EEC)

associated with GHD has been described (OMIM 129900; Table 83-1). Additionally, two brothers with EEC were reported to have pituitary deficits; both had hypogonadotropic hypogonadism and one also had central hypothyroidism. At least three loci have been found for EEC including EEC 1 on 7q, EEC 2 on chromosome 19 and EEC 3 on 3q27. Mutation analysis of the p63 gene, which maps to 3q27, revealed several mutations responsible for EEC 3 (28).

**83.2.2.14 Fanconi Anemia.** Fanconi syndrome is an autosomal recessive disorder characterized by chronic pancytopenia with bone marrow hypoplasia, abnormal pigmentation, upper limb malformations, kidney anomalies, growth retardation, small genitalia, and increased frequency of chromosomal breaks in cultured lymphocytes (OMIM 227650, 227645, 227646, 300514, 600901, 603467, 605724, 609054, 609053; Table 83-1). Nilsson found that 38/68 (56%) of published cases of Fanconi anemia had stunted growth and 24/68 (35%) had genital anomalies. Cussen reported a child with Fanconi anemia, who appeared to be a pituitary dwarf, and pointed out that small pituitary glands, adrenocortical atrophy, and atrophic testes have been described in this syndrome. A number of investigators have now documented GH deficiency in patients with Fanconi anemia, most of whom had no other endocrine deficiencies. A survey of 54 patients, belonging to a number of different complementation groups, in the International Fanconi Anemia Registry revealed that 81% had some type of endocrine disorder, with 44% having abnormal GH stimulation testing and 36% having hypothyroidism; gonadotropins were not assessed in this study (29). Recently, five patients with Fanconi anemia were found to have GH deficiency that responded well to GH therapy, in association with a finding of interrupted pituitary stalk on MRI in all five patients. Three of the five (60%) patients had abnormal TSH levels and two had gonadotropin deficiency (30). These findings suggest that the underlying genetic defect of Fanconi anemia may also affect pituitary development. GHD has also been reported in a patient with Fanconi syndrome with proximal tubule dysfunction (31).

**83.2.2.15 Gonadal Dysgenesis.** Although GH secretion has been reported to be normal in most patients with gonadal dysgenesis, pituitary insufficiency has now been reported in several patients (32). Although the most likely explanation for these cases is a chance association, a hypothalamic disturbance in gonadal dysgenesis has been postulated. Ross and colleagues studied GH secretion in 30 patients with Turner syndrome and found no differences in mean GH concentration or peak amplitudes throughout the day and night between patients less than 8 years of age and controls. Patients over 9 years of age had lower mean GH levels and peak amplitudes. Reduced plasma IGF1 levels and delayed bone age were found in patients of all ages. Deletion of the SHOX gene on the end of Xp is thought to explain a good portion of

the short stature seen in Turner syndrome, as well as with dyschondrosteosis (see Chapters 44 and 158). Despite the presence of normal GH secretion in most Turner syndrome patients, they can have a variable response to GH therapy, and Turner syndrome is now an approved indication for GH therapy.

**83.2.2.16 Hemochromatosis.** Male hypogonadism and pituitary hemosiderosis have long been considered integral features of hemochromatosis (OMIM 235200, Table 83-1). Abnormalities of gonadotropin, cortisol, GH, PRL, and TSH secretion have all been reported. Stocks and Martin demonstrated that functional pituitary insufficiency of varying degrees occurs in 60% of patients with hemochromatosis. Signs and symptoms of gonadal dysfunction included depressed sexual function, testicular atrophy, absent urinary gonadotropins, decreased plasma levels of LH, and low plasma testosterone levels, indicating that the hypogonadism in hemochromatosis is secondary to a deficiency of pituitary gonadotropin. In 7/15 (47%) patients, there was no plasma GH response to hypoglycemia, 6/15 (40%) had an absent or decreased plasma cortisol response to hypoglycemia, and 2/15 (13%) were hypothyroid. The degree of pituitary insufficiency was not related to the severity of the liver disease, nor to the degree of abnormality in either iron or estrogen metabolism.

This pituitary deficiency state appears to be secondary to iron deposition in the anterior pituitary. The testes of hypogonadal patients with hemochromatosis usually show evidence of secondary atrophy without iron deposition, documenting the hypogonadotropic nature of the hypogonadism in this disease. Most studies have reported testicular atrophy with low levels of gonadotropins, and lack of response to gonadotropin-releasing hormone. However, in a 78-year-old man with hemosiderosis secondary to sideroblastic anemia and multiple transfusions, Williams and Frohman documented hypothyroidism and hypogonadism that was hypothalamic in origin (see Chapter 101 for a discussion of the genetics of hemochromatosis).

**83.2.2.17 Neurofibromatosis Type 1.** A variety of endocrine disturbances have been reported in patients with neurofibromatosis type 1 (NF1, OMIM 162200; Table 83-1). Short stature is common, and in one study 50% of patients who attained their adult height during the study were significantly below their predicted adult height. While some studies have found GHD even in the absence of suprasellar tumors and/or neurosurgery or radiation, other studies have found GHD only in patients who had previously undergone intervention for tumor (33). The cause of the short stature in those patients who are not GH deficient is unclear. Precocious puberty can be seen in children with NF1, presumably due to hypothalamic involvement. GH hypersecretion has also been reported in some cases of NF1 (34,35).

**83.2.2.18 Reiger Syndrome.** Reiger syndrome is an autosomal dominant disorder associated with

malformation of the iris, pupillary anomalies, and hypoplasia of the teeth, with or without maxillary hypoplasia. Sadeghi-Nejad and Senior reported a large family in which three and possibly five individuals had both Rieger syndrome and IGHD (OMIM 180500; Table 83-1). Sibs of the proband had Rieger syndrome with normal pituitary function, but GH was not deficient in any member of the family who did not have Rieger syndrome. Affected individuals had insulin hypersensitivity, but normal plasma insulin responded to arginine and glucose. One subject who was treated with GH exhibited substantial enhancement of his rate of growth. It is postulated that the basic pathogenetic mechanism in this autosomal dominant disorder is maldevelopment of the neural crest, resulting in ocular, dental, and hypothalamic abnormalities. The homeobox gene *PITX2* (also called *RIEG*) has been identified as one cause of Rieger syndrome, which is genetically heterogeneous. The mouse homolog gene *Pitx2* is expressed in Rathke's pouch, and mice heterozygous for a *Pitx2* knockout have pituitary hypoplasia. In addition, expression of GH, TSH, and GHRH are decreased in the pituitaries of such mice, and expression of GNRHR and gonatropins is almost absent. Thus, *Pitx2* appears to be an important regulator of pituitary development (36).

**83.2.2.19 Moebius Syndrome.** Moebius syndrome (congenital paralysis of the facial nerves) has been reported in association with various types of pituitary dysfunction. Hashimoto and colleagues described a 17-year-old with Moebius syndrome, GHD, probable hypogonadotropic hypogonadism, and hypoplastic optic discs (OMIM 157900; Table 83-1). Multiple cases of Moebius syndrome in association with isolated hypogonadotropic hypogonadism have also been reported; this association may represent a distinct subtype of Moebius syndrome (37).

**83.2.2.20 Syndromes Reported with Growth Hormone Deficiency.** A number of other syndromes have had occasional reports of associated GH deficiency: Stratton-Parker syndrome (38), Kearns-Sayre syndrome (39), Costello syndrome (40,41), Williams syndrome (42), Langer-Giedion syndrome (43), Duchenne muscular dystrophy (44,45), and amelogenesis imperfecta (46). It remains to be seen how many of these observations are simply chance occurrences.

### 83.2.3 Combined Pituitary Hormone Deficiency

Hereditary forms of pituitary insufficiency represent a genetically heterogeneous group of disorders that can result from interruptions at any point in the hypothalamic-pituitary-IGF1-peripheral tissue axis (Tables 83-2 and 83-3). Most of these disorders result from disruption of normal pituitary development. CPHD is defined as deficiency of any two or more of the pituitary hormones (most commonly GH plus at least one

other hormone). The clinical features of hereditary CPHD are identical to those of the nongenetic forms of the disease and are dependent on which of the hormones are deficient. Deficiency of GH results in proportionate short stature, increased subcutaneous adipose tissue, and characteristic high-pitched voice. Gonadotropin deficiency results in sexual immaturity with primary amenorrhea in females, small testes and phallus in males, and lack of secondary sexual characteristics in both sexes. TSH deficiency most often causes mild hypothyroidism. ACTH deficiency may contribute to severe hypoglycemia in infancy and childhood and may be life threatening. There is both inter- and intrafamilial variability in associated hormonal deficiencies.

**83.2.3.1 CPHD Due to Mutations in *POU1F1*.** In Snell (dw) and Jackson (dw) dwarf mice, mutations in *pit1*, a tissue-specific pou-domain transcription factor, lead to the absence of somatotroph, lactotroph, and thyrotroph cells. Multiple mutations in the human gene *POU1F1* have been found in humans in a subtype of CPHD associated with GH, PRL, and TSH deficiency (omim 613038, Table 83-2). Clinically, some patients present with all hormone deficiencies and growth failure at a young age, while others present with GH deficiency initially and develop TSH deficiency later in their childhood. The appearance of the pituitary on MRI can be either normal or hypoplastic (47). Currently, at least 19 different *POU1F1* mutations are cataloged in the human gene mutation database (HGMD, available online at <http://www.hgmd.cf.ac.uk/hgmd0.html>).

Both autosomal recessive and autosomal dominant inheritance patterns have been reported. The first and second autosomal recessive *POU1F1* mutations were reported in two consanguineous Japanese families. In one family, a C to T transition in codon 172 encoded a CGA (arginine) to TGA (stop) substitution. Both parents were heterozygous, and the affected child was homozygous for the mutation. In the second family, an A to G transition in codon 143 encoding a CGA (arginine) to CAA (glutamine) was found. The patient was shown to be homozygous for this mutation, but the parents and two unaffected siblings were shown to be heterozygous. Both mutations occur in the POU-specific domain and are believed to affect DNA binding.

The third and fourth *POU1F1* mutations were found in two Dutch families who had postnatal growth failure with complete deficiencies of GH and PRL, whereas the T4 levels were low or normal prior to or following GH replacement. Subjects having normal T4 levels were homozygous for a G to C transversion in codon 158 encoding a GCA (alanine) to CCA (proline) substitution. This mutation interferes with the formation of *POU1F1* homodimers and dramatically reduces the ability of the altered *POU1F1* to activate transcription. Additional *POU1F1* mutations with autosomal inheritance have since been reported; the majority are in the POU-specific domain and appear to affect DNA binding

and/or transactivation of transcription. Other autosomal recessive mutations cause premature termination of the protein, creating a nonfunctional product. Compound heterozygotes have also been reported in several instances (47–51).

The first dominant-negative *POU1F1* mutation identified was a G to T transversion in codon 271 that encodes a GGG (arginine) to TGG (tryptophan) substitution. This mutation functions as a dominant inhibitor of *POU1F1* action by some as-yet unknown mechanism. Three unrelated patients have been reported to be heterozygous for this mutation. Two of the patients were evaluated as adults and found to have pituitary hypoplasia and deficiencies of GH, PRL, and TSH. The third patient was identified at only 2 months of age and found to have a normal pituitary and normal basal levels of TSH but a delayed TSH response in a TRH stimulation test. The authors suggest that as *POU1F1* may be necessary for anterior pituitary cell survival, the affected patient will develop hypoplasia and TSH deficiencies with age. The second dominant-negative *POU1F1* gene mutation was a T to C transition in codon 24 that encodes a CCT (proline) to CTT (leucine) substitution. This proline residue resides within the major transactivating domain of *POU1F1* and is highly conserved in different species. The mechanism by which this mutation exerts its dominant-negative effect is also not known.

**83.2.3.2 CPHD Mutations Due to *PROP1* Mutations.** Ames dwarf (*df/df*) mice have CPHD and hypoplastic anterior pituitaries that lack somatotropes, lactotropes, and thyrotropes as well as GH transcripts. The genetic defect associated with the Ames dwarf phenotype perturbs the Prophet of Pit 1 (*Prop1*) gene, which encodes a pituitary-specific homeodomain factor. Sequence analysis of the *Prop1* cDNA in the *df/df* mouse revealed a T to C transition in codon 83 that causes a Ser to Pro amino acid change in the first  $\alpha$ -helix of its homeodomain. Although *Prop1* is required for expression of *Pit1*, how *Prop1* regulates *Pit1* expression remains uncertain.

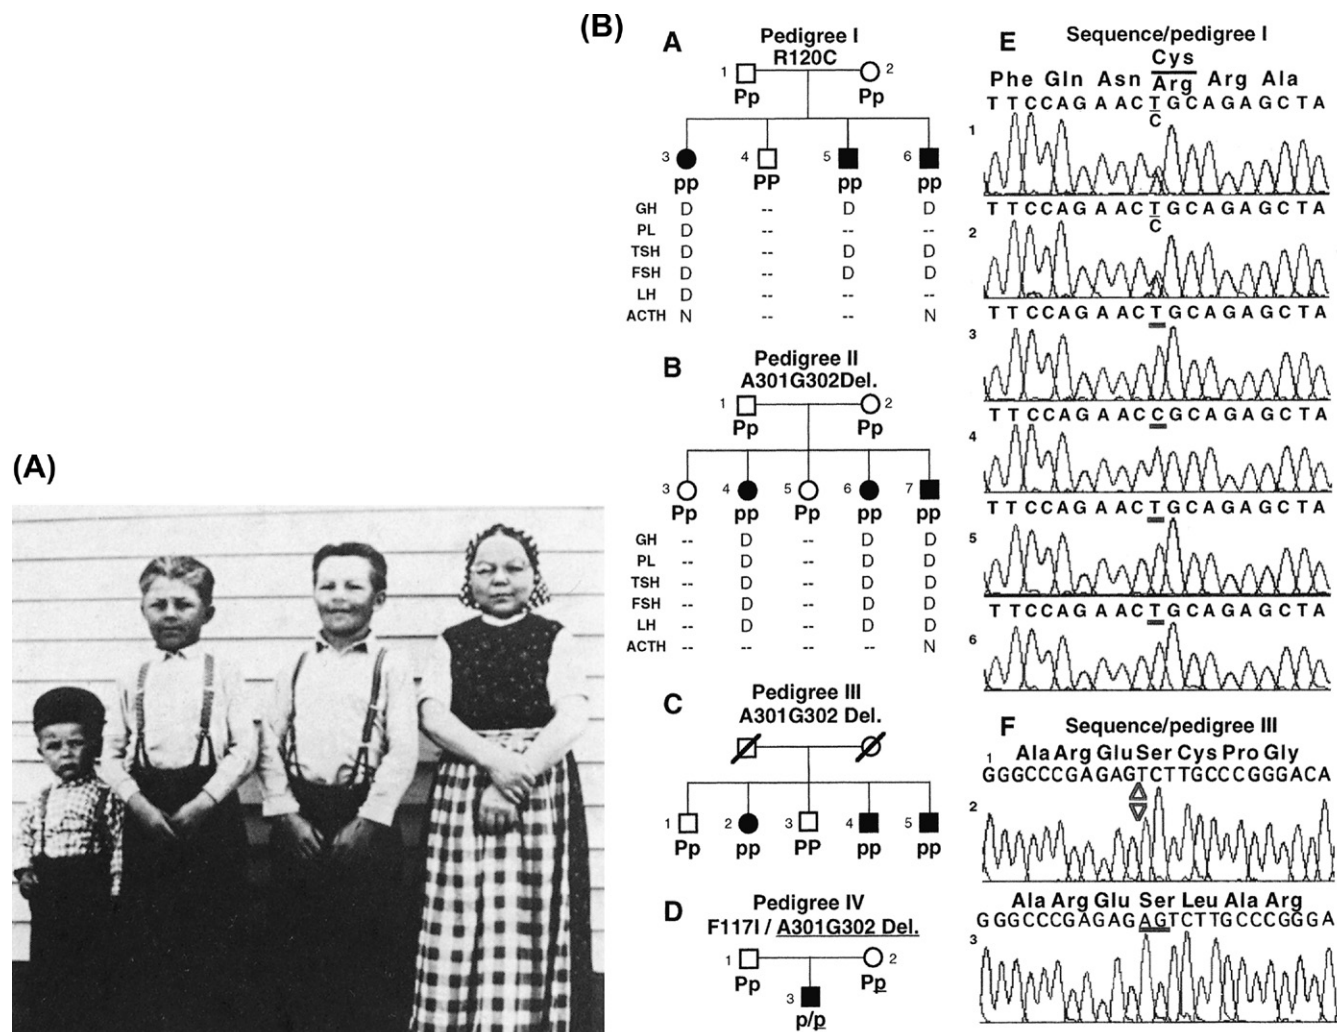

McArthur and colleagues restudied that the Hutterite family illustrated in Figure 83-2 and demonstrated that the tropic hormone loss was sequential. In one sibship, GH and gonadotropin deficiencies occurred in the first decade, with subsequent loss of TSH, and finally, ACTH in the third decade. Subsequently, these patients have been shown to have *PROP1* mutations (Figure 83-2). Since that time, it has become apparent that development of anterior pituitary hormone deficiencies in patients with *PROP1* mutations follows a predictable sequence: GH, TSH, FSH, LH, and ACTH. PRL deficiency is variable. ACTH deficiency may not develop until the fourth or fifth decade of life (52–54). Most patients present with growth failure in childhood; however, some patients may present initially with evidence of central hypothyroidism. Longitudinal imaging studies of patients with *PROP1* mutations show that some patients develop a

pituitary mass, which eventually regresses, while others have anterior pituitary hypoplasia. It has been hypothesized that the pituitary mass arises from the intermediate lobe of the pituitary but this has not been confirmed (53,55,56). There has been one report of a patient with a R120C mutation in *PROP1* who achieved a normal final height; the patient presented with absent puberty. In another family with the more common 101delAG mutation, one affected patient required GH to reach a normal final height, while other affected family members achieved a height in the low normal range with no or inadequate treatment. These cases emphasize the wide range of variable expressivity that is seen in patients with *PROP1* mutations and the need for careful and repeated assessment of pituitary function to detect changes over time (53,57).

Multiple *PROP1* gene mutations have now been identified. The first mutation, identified by Wu et al. in 1998, was a C to T transition in codon 120, which encoded a TGC (Arg) to CGC (Cys) substitution in the third helix of the homeodomain. This mutation greatly reduced DNA binding. The same authors also found a 2-bp deletion in codon 101 (101delAG) that caused a frameshift and resulted in a premature stop at codon 109 (Figure 83-2B, panel F3). This protein product had absent DNA binding. Subsequently, the 101delAG mutation has been found to be a recurring mutation and is estimated to occur in about 55% of familial and 12% of sporadic CPHD cases. The region of the 101delAG mutation contains three tandem repeats (GAGAGA) and appears to be a hot spot for mutations in *PROP1*. Multiple other missense and splicing mutations have been found, most of which occur in the homeodomain region and appear to affect DNA binding (58).

**83.2.3.3 CPHD Due to LIM-Homeobox Gene Mutations.** Mutations in *LHX3* have been associated with a syndrome of CPHD and rigid cervical spine. These patients have deficits in all pituitary hormones except ACTH and have limited head rotation (see Table 83-2). On imaging studies, both pituitary hypoplasia and enlargement have been seen. One missense mutation has been shown to impair activation of gene transcription by the *LHX3* gene product, while another mutation deletes the DNA binding domain and thus also results in an inability to induce transcription (59,60). Kristrom et al. described six unrelated patients with CPHD and limited neck rotation who also had scoliosis and congenital hearing loss. All were found to have the same splice-acceptor site mutation. CT imaging of the neck showed abnormalities of the occipito-atlanto-axial joints, which explained the limited neck rotation (61). Pfaeffle et al. reported four novel mutations, including one (W224Ter) which was associated with CPHD only with normal neck rotation (62).

Machinis et al. reported a consanguineous French family in which two sibs with short stature were found

**FIGURE 83-2** (A) Autosomal recessive CPHD. Three affected Hutterite siblings on the right and their cousin on the left. (B) Pedigrees of CPHD kindreds (left) including B–C, that of the Hutterite family shown in (A) and the DNA sequences of *PROP1* genes (right) including B–F, that of the Hutterite family shown in (A). (From Wu, W., Cogan, J. D., Pfaffle, R. W., et al. *Mutations in PROP1 Cause Familial Combined Pituitary Hormone Deficiency*. *Nat. Genet.* 1998, 18, 147–149.)

to have GH, TSH, and ACTH deficiencies (63). MRI showed that both had small sella turcica, persistent craniopharyngeal canals, hypoplastic anterior hypophyses with associated pointed cerebellar tonsils (as seen in the Chiari malformation), and ectopic posterior hypophyses. The two probands had ectopic posterior pituitaries, which were not found in other relatives. A heterozygous germline mutation of the LIM-homeobox transcription factor *LHX4* was found that cosegregated with the syndrome in this family. Mice null for *Lhx4* have pituitary hypoplasia due to increased cell death (64). Subsequently, additional studies have shown that pituitary deficiencies in patients with *LHX4* mutations may vary, ranging from deficiency of GH only to deficiency of GH, TSH, ACTH, and gonadotropins in varying combinations, even within the same family. Anterior pituitary morphology may range from hypoplastic to normal to enlarged, while the posterior pituitary may be either normally sited or ectopic. Some patients/families may have additional brain abnormalities including abnormal

corpus callosum, Chiari malformation, or abnormal cerebellar tonsils (65–67).

**83.2.3.4 CPHD Due to *HESX1* Mutations.** Like *POU1F1* and *PROP1*, *HESX1* is a transcription factor important in the development of the pituitary. It is a member of the Paired class of homeodomain proteins and functions as a transcriptional repressor. Its role in pituitary development was first discovered in mice; mice null for the mouse homolog *Hesx1* were found to have a phenotype similar to SOD in humans, with abnormal forebrain development, absent or poorly developed eyes, and midline abnormalities including hypothalamic defects and abnormal development of Rathke's pouch. These findings led to the analysis of the human *HESX1* gene in patients with SOD, and a homozygous mutation in the homeodomain region was found in two sibs with agenesis of the corpus callosum and panhypopituitarism. The unaffected parents were heterozygous, consistent with autosomal recessive inheritance. Subsequently, some heterozygous patients have been found to be mildly

affected, with phenotypes ranging from IGHD to CPHD to GHD with optic nerve hypoplasia (68). The mutations found to date appear to affect DNA binding and/or interactions of the HESX1 protein product with other partner proteins (69). Specifically, the I26T mutation impairs the ability of HESX1 to recruit corepressors, with a phenotype of panhypopituitarism associated with anterior pituitary hypoplasia and posterior pituitary ectopia, but without optic nerve defects or other midline brain defects typically seen with SOD (70). Conversely, a mutation, which causes increased binding leading to increased repression of PROP1, has also been identified to cause SOD with GHD (71). A Japanese patient with CPHD with a hypoplastic anterior pituitary, ectopic posterior lobe, and left optic nerve hypoplasia was found to have a heterozygous frameshift mutation (306/307ins AG) in exon 2 of HESX1, which introduced a premature stop codon soon after the mutation site. Therefore, this mutation would be predicted to generate a protein lacking the carboxyl-terminal homeobox (DNA-binding) domain (72).

**83.2.3.5 CPHD Due to OTX2 Mutations.** Defects in OTX2, another pituitary transcription factor, were first identified in patients with microphthalmia syndrome, but it was quickly realized first that some of these patients have pituitary defects as well and that patients can have CPHD due to OTX2 without eye abnormalities. The number and combination of pituitary hormone deficiencies is highly variable. OTX2 is known to interact with HESX1 and affect its expression (73,74).

**83.2.3.6 CPHD Due to X-Linked Mutations.** There are pedigrees in which CPHD appears to be inherited as an X-linked recessive trait. A review of the older reported pedigrees reveals several families with only male siblings affected, compatible with either autosomal recessive with sex-limited expression or X-linked recessive inheritance. A family with four cases of X-linked recessive CPHD was found by Lagerstrom-Fermer and colleagues to show the linkage with markers in the Xq25-q26 region (peak lod score of 4.12) (see OMIM #307200; see Tables 83-2 and 83-3). Further examination revealed an extra copy of the marker DXS102, suggesting a duplication in this region. Solomon et al. identified a pedigree with mental retardation and CPHD and localized the defect to a duplication in the region Xq26.1-q27.3, then narrowed the critical region to a 3.9Mb interval at Xq27.2-q27.3 (75,76). This critical region includes SOX3, an HMG-box protein. A mutation in SOX3 has been shown to cause mental retardation and GHD in a large pedigree (77) and SOX3 has been shown to be essential for pituitary development and function in a mouse model (78). Woods and colleagues found families in which both overdosage and underdosage of SOX3 were associated with similar phenotypes, consisting of infundibular hypoplasia and hypopituitarism, but not necessarily mental retardation (79).

## 83.2.4 Disorders of the Growth Hormone Pathway

The various disorders of GH secretion and function can be classified based on (1) the level of the defect, (2) mode of inheritance, (3) number of hormone deficiencies, (4) complete or partial absence of GH versus defective GH, and (5) receptor function or resistance. This section will focus on those disorders isolated to the GH pathway (Table 83-3).

Proportionate short stature may result from a wide variety of endocrinologic, metabolic, nutritional, emotional, and genetic disorders. Pituitary deficiency has long been recognized as a cause of proportionate short stature, and it is now apparent that these disorders represent a heterogeneous group of disorders secondary to a variety of genetic and acquired defects in GH secretion or action. Defects have been described at all levels of the hypothalamopituitary-IGF1-chondro-osseous end-organ axis (Figure 83-1; Table 83-3). Delineation of the distinct disorder in each patient has implications for genetic counseling; now that both recombinant GH and IGF1 have become available for treatment, an exact diagnosis has therapeutic significance.

The frequency of GH deficiency (either isolated or concomitant with other pituitary hormone deficiencies) is estimated to range from 1/4000 to 1/10,000 in various studies. Most cases are sporadic and are assumed to arise from cerebral insults or defects, including cerebral edema, chromosome anomalies, histiocytosis, infections, radiation, SOD, trauma, or tumors affecting the hypothalamus or pituitary. Hypothalamic or pituitary anomalies are detected by MRI in ~12% of patients who have IGHD.

Estimates of the proportion of GH-deficient cases having an affected parent, sibling, or child range from 3% to 30% in different studies. This familial clustering suggests that a significant proportion of cases may have a genetic basis. The genetics and molecular pathophysiology of familial IGHD are discussed in the following sections.

Adequate amounts of GH are needed throughout childhood to maintain normal growth. Newborns with GH deficiency are usually of normal length and weight. In those with IGHD, skeletal maturation is usually delayed. Truncal obesity, facial appearance younger than expected for chronological age, delayed secondary dentition, and high-pitched voice are often present. Puberty may be delayed until the late teens, but fertility is usually normal. Fine, wrinkled skin appearing similar to that of premature aging is seen in affected adults. In patients with CPHD, the retardation of growth and skeletal maturation is often more severe and spontaneous puberty may not occur.

**83.2.4.1 GHRHR Gene Defects.** The defect in the “little” (lit) mouse is a point mutation in the GHRH receptor (*GHRHR*) gene that results in an Asp to Gly substitution at residue 60. A nonsense mutation has been

reported in the human *GHRHR* gene in two first cousins of a consanguineous Indian Muslim family with profound IGHD (OMIM 139191; Table 83-3). Both cousins were homozygous for a G to T transversion in exon 3, which converted a Glu to Stop in their *GHRHR* genes. Subsequently, the same mutation has been identified in an isolate from the Indus valley of Pakistan. A second mutation has been identified in a large isolate from Brazil diagnosed with an autosomal recessive form of IGHD. Affected subjects were found to be homozygous for a G to A transition of the first base of IVS1, which is predicted to alter splicing, and results in an inactive protein product.

Mutations in *GHRHR* are emerging as a relatively common cause of inherited autosomal recessive IGHD. The first human *GHRHR* mutations were discovered in families with a history of parental consanguinity. More recently, kindreds in which IGHD subjects are compound heterozygotes for two distinct mutations have been reported, suggesting that mutant *GHRHR* alleles may need to be considered even in sporadic IGHD cases. Mutations in the *GHRHR* gene are usually associated with anterior pituitary hypoplasia (APH, defined as pituitary height more than 2 SDS below normal). Alba and colleagues demonstrated that pituitary height may fall within two SDS from the norm in patients with severe IGHD due to a homozygous *GHRHR* mutation, and that pituitary size may vary within patients with identical mutations who belong to the same family (80).

**83.2.4.2 Familial IGHD.** From 3% to 30% of GHD cases have an affected parent, sib, or child. This familial clustering suggests that a significant proportion of cases

may have a genetic basis. Familial IGHD is associated with at least four Mendelian disorders (Table 83-3). These include two forms that have autosomal recessive (IGHD IA and IB) inheritance, as well as autosomal dominant (IGHD II) and X-linked (IGHD III) forms. A variety of molecular defects have been detected that cause these disorders (Table 83-4). IGHD IA and IB as well as IGHD II are caused by defects in *GH1*. There are 56 *GH1* mutations documented to date in the HGMD. These defects will be reviewed under the type of inheritance (IGHD I-III) that they cause.

**83.2.4.3 IGHD IA.** The most severe form of IGHD, called IGHD IA, has an autosomal recessive mode of inheritance (OMIM 139250, Table 83-3). Affected individuals occasionally have short lengths at birth and hypoglycemia in infancy, but uniformly develop severe dwarfism by 6 months of age. In response to replacement therapy with exogenous GH, IGHD IA subjects have a strong initial anabolic and growth response that is frequently followed by the development of anti-GH antibodies in sufficient titer to block the response to GH replacement. These features led Illig and colleagues to hypothesize that IGHD IA caused complete prenatal and postnatal deficiency of endogenous GH secretion, resulting in an immune response to exogenous GH.

**83.2.4.4 Deletions.** Initially, all individuals with IGHD IA were found to be homozygous for *GH1* gene deletions (Figure 83-3; Table 83-4), and they developed anti-GH antibodies with treatment. Subsequently, additional cases with *GH1* gene deletions have been described who also have complete GH deficiency but respond well to GH replacement. Thus, the clinical outcomes of subjects

**FIGURE 83-3** IGHD type IA. Autoradiogram patterns of DNA from three Swiss families and three controls. Note absent bands in homozygous affected patients. (From Phillips, J. A. III; Hjelle, B. L.; Seeburg, P. H., et al. *Molecular Basis for Familial Isolated Growth Hormone Deficiency*. Proc. Natl. Acad. Sci. USA. 1981, 78, 6372–6375.)

with the same molecular findings (homozygosity for *GH1* gene deletions) vary, making the presence of anti-GH antibodies an inconsistent finding in IGHD IA cases.

At a molecular level, Southern blot analysis showed deletions of ~6.7, 7.0, or 7.6 kb (kilobase), with most (~75%) being 6.7 kb. DNA sequence analysis of the fusion fragments associated with *GH1* gene deletions has shown that homologous recombination between sequences flanking the *GH1* gene causes these deletions (Figure 83-3). This same mechanism has been shown to cause deletions of the beta-globin and low-density lipoprotein receptor genes in some subjects with beta thalassemia or familial hypercholesterolemia, respectively. In the past, *GH1* gene deletions were detected using polymerase chain reaction (PCR) amplification of the homologous regions flanking the *GH1* gene and the fusion fragments associated with *GH1* gene deletions. Inasmuch as the fusion fragments associated with 6.7 kb deletions differ in the size of fragments produced by certain restriction enzymes, homozygosity, or heterozygosity for these deletions can easily be detected by enzyme digestion of PCR products. More recently, multiplex ligation-dependent probe amplification (MLPA) has been used to detect *GH1* and other selected deletions. MLPA is a variation of PCR that enables multiple targets such as different exons of a target gene to be amplified with only a single primer pair. By comparing, the peak pattern obtained on a given sample with that obtained on reference samples, the relative quantity of each amplicon and exon can be determined (81).

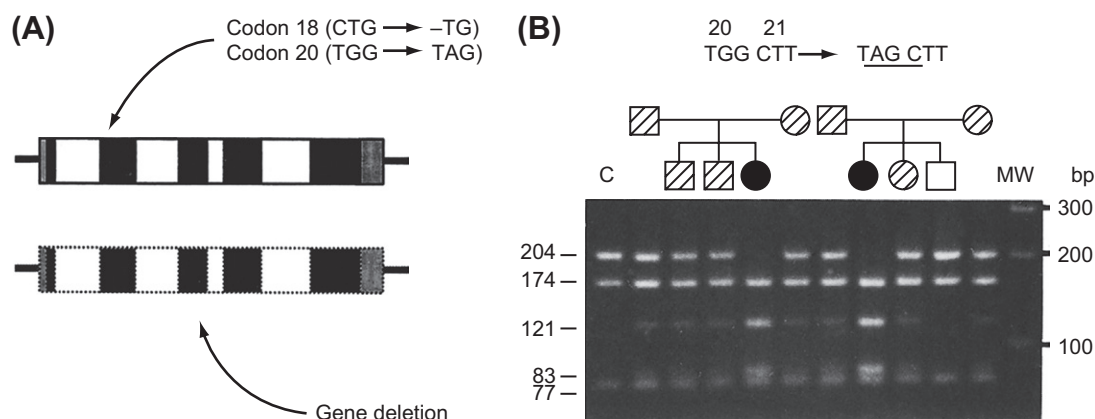

A variety of studies suggest that 13–15% of subjects with severe IGHD ( $\geq -4.5$  SD in height) have *GH1* gene deletions. Recently, frameshift and nonsense mutations have also been found in subjects with the IGHD IA phenotype, so that this disorder may best be described as complete GH deficiency due to *GH1* gene defects rather than to gene deletions alone.

**83.2.4.5 Deletion/Frameshift Mutations.** Two affected sibs with IGHD IA have been reported who

are compound heterozygotes for deletion and frameshift mutations of the *GH1* gene. Southern blot analysis showed them to be heterozygous for the 6.7 kb *GH* gene deletion. DNA sequence analysis of cloned copies of the *GH1* gene showed deletion of a cytosine at position 371 (Table 83-4). This single-base deletion results in a frameshift within the signal peptide-coding region and prevents the synthesis of any mature GH protein. The patients presented with severe growth failure and, after an initial growth response to treatment with exogenous GH, developed high titers of anti-GH antibodies.

**83.2.4.6 Nonsense Mutation.** A G to A transition in codon 20 that encodes a tryptophan (TGG) to a stop (TAG) codon substitution of the GH signal peptide has been reported in a consanguineous Turkish family with IGHD IA (Figure 83-4A). This results in the termination of translation after residue 19 of the signal peptide and no production of mature GH. Patients homozygous for this mutation have no detectable GH and produce anti-GH antibodies in response to exogenous GH treatment. Interestingly, this mutation generates a new *AluI* site that can readily be screened by PCR amplification of the GH gene, followed by *AluI* digestion and gel electrophoresis (Figure 83-4B).

**83.2.4.7 IGHD IB.** The second autosomal recessive form of IGHD is type IB (OMIM 139250; Tables 83-3 and 83-4). This disorder is associated with proportionate short stature, increased subcutaneous fat, and typical pinched facies, with high forehead, wrinkled skin, and high-pitched voice (Figure 83-5A; Tables 83-3 and 83-4). Plasma GH is deficient, but is clearly detectable after provocative stimuli. Deficient growth velocity responds quickly and consistently to GH therapy and patients do not develop high titers of blocking antibodies. They may have spontaneous hypoglycemic episodes in infancy but this is not a problem after early childhood, although they maintain hypersensitivity to exogenous insulin into adulthood. As adults, abnormal glucose tolerance associated with insulinopenia is a characteristic feature; both

**FIGURE 83-4** (A) Schematic representation of the *GH1* gene showing the locations of various IGHD IA mutations. (B) Detection of a G to A transition that encodes a Trp to Stop substitution at codon 20 by digestion with *AluI* restriction enzyme and gel electrophoresis. Note, when this mutation is present a new *AluI* recognition site occurs and the normal 204 bp fragments are cleaved to 121 and 83 bp.

quickly revert to normal following GH therapy. Puberty occurs spontaneously, but is frequently delayed to the late teens or early 20s. Puberty frequently appears abruptly during the first few months of GH therapy. Thus, in the prepubertal individual, IGHD cannot be clinically distinguished from a combined deficiency of GH and gonadotropins until at least the early 20s. LHRH stimulation studies may distinguish between these two disorders.

Autopsy studies in three cases of IGHD IB have all revealed the presence of typical somatotrophic cells in the pituitary and, in the one case assayed, the presence of significant amounts of immunoreactive GH. Although the relative numbers of somatotrophic cells in the pituitary differed between the three cases studied, they clearly demonstrated the pituitary's ability to synthesize GH. Administration of GHRH to two sibs with IGHD IB resulted in a significant rise in plasma GH levels. Sporadic cases of IGHD have been found to vary in their response to GHRH, suggesting that IGHD can occur secondary to either hypothalamic or pituitary defects. To date, the *GH1* gene has been present in all individuals with this syndrome who have been studied. Phillips and

colleagues found that in the majority of families with IGHD IB, the disease did not cosegregate with RFLPs at the GH gene cluster. Thus, the defects in IGHD IB may include deficiencies of GHRH synthesis or secretion or defects in GHRHR (see following). Further locus heterogeneity must be excluded.

*GH1* gene defects have been found in three families originally diagnosed with IGHD IA owing to the severity of growth retardation and apparent lack of endogenous GH as determined by RIA. They have been reclassified as having IGHD IB because of the nature of their *GH1* gene defects and their failure to produce anti-GH antibodies in response to treatment with endogenous GH (Fig. 83-5B; Table 83-3).

**83.2.4.8 Splicing Mutations.** A G to C transversion on the first base of the donor splice site of intron IV was detected in a consanguineous Saudi Arabian family with IGHD IB (Figure 83-5B; Tables 83-3 and 83-4). The effect of this mutation on mRNA splicing was determined by transfecting the mutant gene into cultured mammalian cells and sequencing the resulting GH complementary DNAs (cDNAs). The mutation was found to cause the activation of a cryptic splice site 73 bases upstream of the exon IV donor splice site. This altered splicing results in the loss of amino acids 103–126 of exon IV and creates a frameshift that altered the amino acids encoded by exon V. Such changes in the amino acids encoded by exons IV and V may not only affect the stability and biologic activity of the mutant GH protein but, as studies with bovine GH mutants have shown, may also derange intracellular targeting of GH protein products to the secretory granule. A G to T transversion has been identified at the same site in another consanguineous Saudi family (Figure 83-5B). Analysis of GH mRNA transcripts from the lymphoblastoid cells of affected patients confirmed that the G to T transversion had the same effect on splicing as the G to C transversion. Both of these mutations destroy an HphI site that enables their detection by restriction digestion of PCR products containing the GH mutation followed by gel electrophoresis. Patients homozygous for these different defects in two different families responded well to exogenous GH treatment and did not make anti-GH antibodies, suggesting that GH proteins may be released that protect against an immune response to exogenous GH.

A G to C transversion of the fifth base of intron IV of *GH1* was identified in a highly consanguineous family diagnosed with IGHD IB (Figure 83-5B). This mutation created a new Mae II site, which was used to screen all family members for the mutation. RT-PCR analysis of GH mRNA transcripts from the lymphoblastoid cells of an affected patient demonstrated that the mutation destroyed the intron IV donor splice site and had the same overall effect on splicing as the +1G to C transversion described previously. Analogous splicing mutations occur in the beta-globin gene, causing milder forms of beta thalassemia, as well as in many other genes.

**FIGURE 83-5** (A) Autosomal recessive IGHD type 1B in two siblings who are the offspring of a consanguineous mating. (B) Schematic representation of the *GH1* gene showing the locations of various IGHD IB mutations.

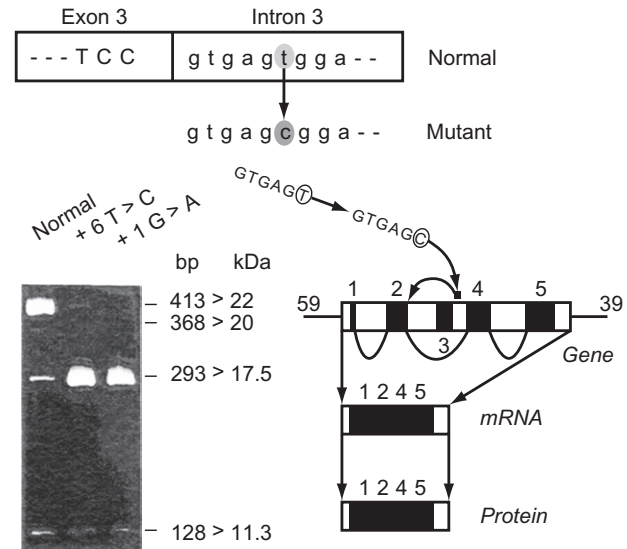

**83.2.4.9 Deletion/Frameshift Mutations.** A patient with severe growth retardation diagnosed with IGHD was found to be a compound heterozygote for mutations at the *GH1* gene locus. PCR followed by restriction enzyme digestion showed the patient to be heterozygous for the 6.7kb deletion. DNA sequence analysis of the GH gene revealed a 2-bp deletion in exon III of the second GH1 allele (Figure 83-5B; Table 83-4). This 2-bp deletion results in a frameshift within exon III and generates a premature stop codon at the position of amino acid residue 132 in exon IV. The patient had a positive response to GH replacement therapy and did not produce anti-GH antibodies, again suggesting that some GH-related protein is produced.

#### 83.2.4.10 IGHD II.

**83.2.4.10.1 Introduction.** IGHD II is an autosomal dominant disorder that is usually caused by heterozygosity for splicing mutations that increase GH1 exon 3 skipping (Figure 83-6). IGHD II cases vary in severity but respond well to exogenous GH because they do not typically develop neutralizing antibodies. The first IGHD II mutations identified were point mutations at the 5' or donor splice site of IVS3 of GH1 that caused skipping of exon 3 by impairing U1 snRNP recognition and spliceosome assembly (Figure 83-6). Other IGHD II mutations occur at the 3' splice site in IVS2 (82,83).

**83.2.4.10.2 Theoretical Basis of IGHD II.** Why these splicing mutations cause IGHD II remains poorly understood. Haploinsufficiency is unlikely because individuals who are heterozygous for GH1 deletions do not have GHD. A gain of function effect for the 17.5 kD isoform is also unlikely given its inactivity on GH receptors. A dominant-negative mechanism has long been suggested because of the autosomal dominant mode of inheritance and the cosegregation of GH1 and the low serum GH responses of IGHD II cases in response to GHRH.

There have been a variety of hypotheses for the dominant-negative mechanism of the 17.5 kD isoform (84–87). First, since loss of exon 3 results in an unpaired cysteine, Cogan and colleagues hypothesized that this could form aberrant intermolecular disulfide bonds that disrupt secretion of 22 kD GH. However, Lee et al. showed that replacing the free cysteine with an alanine did not correct the secretory defect in GH4C1 cells (87). Second, Lee et al. reported that the 17.5 kD isoform decreased the stability of the 22 kD isoform in neuroendocrine cells by 50% (87). While this supports a dominant-negative effect, a 50% reduction in stability does not explain IGHD II, since patients have little or no detectable GH on GHRH stimulation. Third, the 17.5 kD isoform inhibits secretion of the 22 kD isoform in secretory cell lines (87), without affecting PRL secretion or overall cell function or viability. Fourth, overexpression of the 17.5 kD isoform in COS7 cells disrupted the Golgi apparatus and, in contrast to previous results, impaired overall protein trafficking, specifically inhibiting secretion of PRL and trafficking of TRH receptor to

**FIGURE 83-6** IGHD II is caused by exon 3 skipping. Note the effects of IVS 3 mutations on cDNA (left) and mRNA (right).

the cell membrane (86). Collectively, these data suggest that the 17.5 kD isoform impairs 22 kD GH secretion by inhibiting protein trafficking. However, none of these hypotheses fully explained the complete deficiency of GH secretion that is seen in IGHD II cases.

To determine why GH1 mutations that give rise to products lacking exon 3 cause IGHD II, McGuinness et al. used cell culture and transgenic approaches (88). GC cell lines were generated that express either wild-type GH (WT-hGH-GC) or a GH1 mutation encoding a G to A transition at the 5' splice site of IVS3 ( $\Delta$ exon3hGH-GC) (88). WT-hGH-GC cells grew normally and produced equivalent amounts of human and rat GH packaged in dense-core secretory vesicles (SVs). In contrast,  $\Delta$ exon3hGH-GC cells showed few SVs but instead accumulated secretory product in amorphous cytoplasmic aggregates. They produced much less rat GH and grew more slowly than WT-hGH-GC cells. WT-hGH-GC cells co-transfected with a GH-eGFP construct that co-packages with GH in SVs showed normal morphology and individual SV movements, tracked with confocal and TIRF microscopy in living cells. In contrast, co-expression of  $\Delta$ exon3hGH with GH-eGFP in GC cells abolished the vesicular trafficking of GH-eGFP, which accumulated in motionless aggregates. When  $\Delta$ exon3hGH was targeted to somatotrophs in transgenic mice, it induced a syndrome of autosomal dominant GHD, with mild to severe pituitary hypoplasia and dwarfism evident at weaning in the most severely affected lines (Figure 83-7). Pituitary somatotrophs in  $\Delta$ exon3hGH transgenic mice showed gross disruption of cellular morphology, with very few GH SVs detectable by immunogold EM. In  $\Delta$ exon3hGH transgenic mice, hypothalamic GHRH expression was upregulated, while somatostatin expression was reduced, consistent with profoundly reduced GH feedback. The least affected transgenic line showed milder pituitary

**FIGURE 83-7** Model of constitutive (A) and aberrant (B) GH1 splicing. Wild-type mice express the 22 kD isoform of GH and have normal pituitary morphology with abundant secretory granules and normal phenotype (A).  $\Delta$ exon3 mice (see text) express the 17.5 kD isoform of GH and show replacement of secretory granules by amorphous aggregates (B). This results in somatotroph death with pituitary hypoplasia and dwarfism. (From Ryther, R. C.; McGuinness, L. M.; Phillips, J. A. III, et al. *Disruption of Exon Definition Produces a Dominant-Negative Growth Hormone Isoform that Causes Somatotroph Death and IGHD II*. *Hum. Genet.* **2003**, 113, 140–148.)

deficits relatively specific for GH, while the severely affected lines with higher transgene copy numbers showed early, widespread pituitary damage, macrophage invasion, and multiple hormone deficiencies (88).

**83.2.4.10.3 Transgenic Model of IGHD II.** In the  $\Delta$ exon3 mice, the 17.5 kD isoform progresses through the regulated secretory pathway to form complexes with the WT 22 kD isoform (88). Since the 17.5–22 kD complexes are stable but cannot exit efficiently via SVs, both proteins accumulate in the Golgi and the ER. This triggers a response to the misfolded protein and the complexes are transported into the cytosol (Figure 83-7). McGuinness et al. conclude that when the ratio of 17.5:22 kD isoforms exceeds the degradative capacity of the proteasome pathway, toxic aggregates accumulate in the cytosol, ER, and Golgi. For cells producing GH in culture, autolytic cell death occurs. Interestingly, this is greatly accelerated in  $\Delta$ exon3 mice by trophic drive from GHRH to expand the (defective) somatotroph population and by macrophage invasion that destroys defective cells (88). Mutations identified in ESE1, ESE2, and ISE also increase exon 3 skipping and synthesis of the 17.5 kD isoform that causes IGHD II (89). Ryther et al. also found that artificial SE mutations that weaken exon 3 recognition lead to the production of variable amounts of the 17.5 kD isoform (89). They hypothesize that variations in the severity of IGHD II correlate with the relative levels of the 22 and 17.5 kD isoforms and explain the clinical variability seen in IGHD II.

**83.2.4.10.4 Correlation of IGHD II Severity with Mutant/Normal Transcript Ratios.** We hypothesized that the relative ratios of mutant/normal transcripts in patient-derived cultured lymphocytes (CLs) from a pedigree with an exon 3 skip mutation (Figure 83-8) would correlate with their IGHD II severity. This hypothesis is based on the 17.5-kDa transcript having a dominant-negative effect, and increased levels of expression have

**FIGURE 83-8** Pedigree of the kindred with the E3 + 1 G/A dominant mutation that causes exon 3 skipping. Solid circles and boxes represent affected individuals. The letter “T” represents individuals whose CL-derived RNA was tested for GH1 transcripts by real-time PCR. Numbers below the boxes and circles represent Ht SDS before treatment. (From Hamid, R.; Phillips, J. A. III; Holladay, C., et al. *A Molecular Basis for Variation in Clinical Severity of Isolated Growth Hormone Deficiency Type II*. *J. Clin. Endocrinol. Metab.* **2009**, 94, 4729–4734. Copyright 2009, The Endocrine Society.)

been shown to be cytotoxic to pituitary cells. As shown in Figure 83-9, the relative ratio of 17.5/22-kDa transcripts statistically correlated with Ht SDS ( $P = 0.001$ ), indicating that expression levels of both the mutant and normal *GH1* allele are important in the pathogenesis of IGHD II. These results also suggest that more than ~80% of the variation in Ht SDS is attributable to differences in the isoform ratios. In agreement with this, we note that III-6 who has the highest mutant/normal ratio also has the lowest Ht SDS (Figure 83-9) and GH peak as well as a hypoplastic anterior pituitary (data not shown). In contrast, I-2 and II-5, who have among the lowest mutant–normal ratios of all the family members with IGHD II, also have Ht SDS of –1.96 despite having never been treated with GH replacement (90).

**83.2.4.10.5 Variable Expressivity of IGHD II.** Variable expressivity is regularly seen in IGHD II pedigrees that contain affected individuals whose heights vary, and even without treatment, some may be of normal height. One hypothesis to explain this is that *GH1* mutation that causes IGHD II is not the only determinant of the final height, and thus other “modifying” genes may play an important role in the final phenotype. Knowledge about these modifying genes is still lacking. Our data suggest that one of the important modifiers of IGHD II severity may be variations in the ratios of *GH1* transcripts from both the normal and the mutant IGHD II alleles. Reports that variation of expression of the alleles modifies disease phenotype are rare but are noted for a small number of autosomal dominant diseases (91–93). Observing this variation raises the question of what regulates *GH1* transcript/protein expression. Our segregation studies show that expression levels for the same mutant and normal *GH1* alleles are not allele specific because sibs with disparate Ht SDS inherited the same parental mutant and normal *GH1* alleles. Our segregation data suggest that transcript levels and ratios can differ between sibs such as III-6 and III-7, presumably due to differences

**FIGURE 83-9** (A) 17.5-kDa (gray) and 22-kDa (black) GH1 transcript levels as measured by relative real-time PCR analysis. (B) The relative transcript ratios of 17.5-kDa/22-kDa in CL cell lines derived from the kindred presented in Figure 83-8. Numbers above the columns in panel B represent Ht SDS. Question mark indicates that Ht SDS of II-2 is not known. Family member II-4 was not included in the figure because we could not calculate his Ht SDS due to missing height information (his relative transcript ratio was 0.1, as would be expected for a normal person); additionally, because this person married into the kindred, we felt that he would not be an appropriate control. Each sample was done in triplicate, and analysis was repeated three times. Error bars represent SEM. (From Hamid, R.; Phillips, J. A. III; Holladay, C.; et al. *A Molecular Basis for Variation in Clinical Severity of Isolated Growth Hormone Deficiency Type II*. *J. Clin. Endocrinol. Metab.* **2009**, 94, 4729–4734. Copyright 2009, The Endocrine Society.)

in *trans*-acting factors and/or altered splicing efficiency rather than *cis*-acting factors (90).

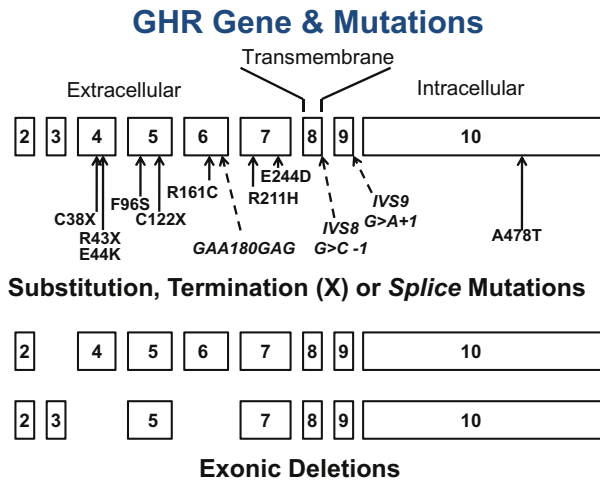

#### 83.2.4.10.6 Experimental Treatment of IGHD II.

Allele-specific degradation of mRNAs encoding the 17.5 kD isoform is a possible way to approach for therapy for individuals with IGHD II. Because numerous *in vivo* (88,89) and *in vitro* (86,87) experiments suggest that normal GH secretion depends, in part, on avoiding increased levels of the 17.5 kD isoform, Ryther et al. concluded that therapies specifically targeting the 17.5 kD isoform might be useful in treating IGHD II. To exclusively target skipped transcripts for degradation, Ryther et al. utilized RNA interference (RNAi) employing silencing RNAs (siRNAs) (Figure 83-10) (94). The exon 2–4 junction was selected as the siRNA target because it is the only sequence unique to transcripts encoding the 17.5 kD GH1 isoform. Plasmids expressing this siRNA (17.5-si) or a random dsRNA sequence (control-si) were cotransfected with either wt GH1 or GH1 enhancer mutants (ESEM and ISEM1) that produce more skipped transcripts. Splicing patterns and actin expression levels were analyzed by RT-PCR. Interestingly, the 17.5-siRNA construct reduced the skipped transcripts by more than 95%, while having no effect on either the FL or cryptic mRNAs (Figure 83-10B). Similar analyses with dsRNA identical to the 17.5-si sequence showed a greater than 90% decrease in skipped mRNAs without affecting the FL or cryptic mRNAs (data not shown). We conclude that siRNAs can specifically degrade 17.5 kD isoform

mRNA, suggesting that this strategy could be effective in preventing production of sufficient dominant-negative 17.5 kD mRNA to cause IGHD II.

**83.2.4.10.7 Summary.** GH1 mutations that cause exon 3 skipping include those in the donor splice site of IVS 3, as well as exon splice enhancers (ESEs) and intron splice enhancers (ISEs). These heterogeneous that perturb splicing result in a 17.5 kD isoform that causes IGHD II in humans and dose-dependent disruption of GH SVs in GC cells and transgenic mice (Figure 83-7) (89). Ryther et al. found that dual SEs are required to ensure the exon 3 definition that produces 22 kD GH (94). Artificial SE mutations that weaken exon 3 recognition lead to the production of variable amounts of the 17.5 kD isoform. We hypothesize that variations in the severity of IGHD II correlate with the relative amounts of 22 and 17.5 kD. Interestingly, Ryther et al. found that siRNAs specific for mRNAs encoding the 17.5 kD isoform could be used to specifically degrade these transcripts in transfected cells (94). If siRNAs could be used in patients to destroy deleterious transcripts such as those causing IGHD II, this approach might provide a potential new avenue of therapeutic intervention for individuals with IGHD II and other dominant and dominant-negative disorders.

Mullis et al. found marked clinical variability in the severity of the IGHD II phenotype, depending on the GH1 gene alteration (95). On follow-up, a number of these patients developed other pituitary hormone

**FIGURE 83-10** Destruction of the 17.5kD messenger by allele-specific siRNA. (A) GH1 constructs expressing wt or ESE mutations were co-transfected with 17.5 kD or control siRNAs. (B) Note knock-down of 17.5kD transcripts in presence of 17.5kD siRNAs. (From Ryther, R. C.; Flynt, A. S.; Harris, B. D., et al. *GH1 Splicing Is Regulated by Multiple Enhancers Whose Mutation Produces a Dominant-Negative GH Isoform that can be Degraded by Allele-Specific Small Interfering RNA (siRNA)*. *Endocrinology*. 2004, 145, 2988–2996.)

deficiencies, mainly ACTH and TSH, especially those that developed a more hypoplastic pituitary gland with time. It is possible that destruction of pituitary somatotrophs by the dominant-negative mechanism above leads to destruction of other cell lines, but this remains to be proved.

**83.2.4.11 IGHD III.** Fleisher et al. described a kindred in which two brothers and their two maternal uncles had a syndrome consisting of hypogammaglobulinemia and IGHD (OMIM 307200; [Table 83-3](#)). They had proportionate short stature, retarded bone age in childhood, delayed onset of puberty, lack of plasma GH response to insulin–arginine stimulation, low bio- and immunoassayable IGF1, and normal TSH, ACTH, FSH, and LH secretion. Recurrent sinopulmonary infections were a problem in two patients, which were abated by parenteral globulin therapy. Three of the patients had pan-hypogammaglobulinemia and absence of circulating B cells, whereas the other patient had normal serum IgA and IgM levels and decreased levels of circulating B cells. All had an absence of specific in vitro antibody production after antigenic stimulation and a failure of in vitro immunoglobulin production. Two of the patients had normal-appearing tonsils. T-cell function and numbers were normal. One of the patients was treated with exogenous GH and developed detectable circulating B lymphocytes, as well as higher levels of IgA, IgM, and IgE than his affected relatives.

Affected individuals in some kindreds have agammaglobulinemia associated with their IGHD, but others do not. This suggests that contiguous gene defects of Xq21.3-q22 may occur in some cases. Interestingly, other cases of IGHD have been found to have an interstitial

deletion of Xp22.3 or duplication of Xq13.3-q21.2, suggesting that multiple loci may cause IGHD III.

**83.2.4.12 Kowarski Syndrome (Bioinactive Growth Hormone).** A number of patients have been described with the clinical features of IGHD who achieved normal plasma immunoactive GH levels following stimulation, but low levels of IGF1 (OMIM 139250; [Table 83-3](#)). Less GH was detected by radioreceptor assay than by radioimmunoassay. Following GH administration, however, they generated normal IGF1 levels and had a significant increase in their growth rates. TSH and ACTH secretion was normal. In view of their clinical syndrome of IGHD, normal plasma GH, low basal IGF-levels, and their normal response to exogenous GH, they appear to secrete a biologically inert GH. As their endogenous GH reacted normally in the immunoassay, this appears to represent a cross-reactive material (CRM) positive mutation.

Valenta et al. reported a similar patient with short stature and normal levels of immunoreactive GH but decreased radioreceptor activity. This patient responded well to exogenous GH, but his plasma IGF1 level was normal. When analyzed by column chromatography his GH exhibited unusual patterns, with most of it migrating as large tetramers or dimers. However, there is a question as to whether his growth failure occurred before age 8 years.

Takahashi et al. identified a C to T transition in codon 77 that results in an Arg to Cys substitution in the GH1 gene of a subject diagnosed with bioinactive GH (OMIM 139250; [Table 83-3](#)). The patient was heterozygous for the mutation, and isoelectric focusing of his serum showed an abnormal GH peak in addition to a normal peak. Surprisingly, his father was also heterozygous for the C to T transition but was of normal height and had normal isoelectric focusing results. The disparate findings in the father and his affected child were not explained.

Besson et al. identified a missense mutation (G705C) in the GH1 gene of a Serbian patient with short stature ([96](#)). This mutation was found in the homozygous state and led to the absence of the disulfide bridge Cys-53 to Cys-165. Thus, GH-C53S is a bio-inactive GH at the physiological range and the disulfide bridge Cys-53 to Cys-163 appears to be required for mediating the biological effects of GH.

By contrast, a number of patients have been described with “invisible GH,” that is, individuals with normal growth, deficient GH secretion as measured by radioimmunoassay, but normal GH concentrations as measured by radioreceptor assay. Thus, these individuals appear to secrete a mutant molecule with normal biological activity which is “invisible” to GH radioimmunoassay. Bis-tritzer et al. postulated that this unusual molecule could be expressed from the *GH-V* gene.

**83.2.4.13 Growth Hormone Secretagogue Receptor (GHSR) Defects.** GHSR (OMIM 601898) is a G-protein-coupled receptor highly expressed in the pituitary and hypothalamus. First recognized as a receptor

for exogenous stimulators of growth hormone secretion, its endogenous ligand Ghrelin (GHRL, OMIM 605353) was identified in 1999. Ghrelin has pleiotropic effects on many body systems and is an orexigenic hormone, but it is also known to release GH, suggesting that it or its receptor GHSR might be involved in short stature. In 2006, Pantel et al. identified a GHSR mutation, A204E, in two unrelated families with apparent idiopathic short stature (ISS). The pedigrees suggested autosomal dominant inheritance with more severe expression in one patient who was homozygous. This amino acid is conserved across all species studied so far and the substitution indicates a significant change in charge. In vitro studies showed that the mutation selectively impaired the constitutive activity of GHSR (97). Subsequently, the same group identified a patient who was a compound heterozygote for two mutations in GHSR. The heterozygous parents were unaffected suggesting autosomal recessive inheritance. The patient had laboratory studies consistent with IGHD and responded well to GH. The mutations also showed reduced constitutive activity of the receptor (98).

**83.2.4.14 Growth Hormone Resistance.** The GHR is localized to human chromosome 15p13.1-p12 and to mouse chromosome 15. The human *GHR* gene spans at least 87kb, making it over 40 times larger than the *GH1* gene, and contains 9 exons (numbered 2–10), whereas exons 2–9 are small, ranging from 66 to 179 bp, exon 10 is large and spans about 3400 bp. The signal peptide and extracellular portions of the GHR that correspond to the GHBP are encoded by exons 2 and 3–7, respectively. The transmembrane and cytoplasmic portions of the GHR are encoded by exons 8 and 9–10, respectively. Currently, 70 mutations have been described in GHR (Table 83-4).

**83.2.4.14.1 GHR Expression.** The extracellular domain of the GHR is normally found in serum as GHBP. The binding affinity of GHBP for GH is about the same as that of intact GHR. The GHBP is thought to arise by alternative splicing of GHR mRNA or proteolysis of the mature GHR peptide. Evidence for alternative

splicing was provided by the detection of multiple GHR transcript sizes by Northern blot analysis. The binding complex formed between GH and a slightly truncated form of GHBP (residues 1–238) is a heterotrimer consisting of one molecule of GH plus two molecules of the truncated GHBP. In this novel process, the second truncated GHBP molecule can bind to GH only if the first truncated GHBP molecule is already bound.

The transmembrane domain of the GHR is encoded by exon 8 and contains 30 residues (Figure 83-11). This portion of the receptor functions as an anchor to position the extracellular and cytoplasmic portions of the GHR molecule correctly in relation to the cell membrane.

The cytoplasmic domain of the GHR is encoded by exons 9 and 10 and contains residues 277–620 (Figure 83-11). This segment of about 350 amino acids functions in signal transduction. The box 1 site, amino acids 276–287, is constitutively associated with janus kinase 2 (jak2); box 2 (amino acids 325–338) is required for full activation of Jak2. The GHR also interacts directly with Stat5.

**83.2.4.14.2 GHR Gene Defects.** Laron dwarfism type 1 is an autosomal recessive disorder caused by target resistance to the action of GH (Figure 83-1). Laron and colleagues described a syndrome with the clinical features of pituitary dwarfism, associated with high plasma concentrations of immunoreactive GH (Figure 83-12; OMIM 262500; Table 83-3). Although their patients were all oriental Jewish, this autosomal recessive syndrome has since been described in numerous other ethnic groups. These individuals have the clinical appearance of patients with IGHD to an exaggerated extent, with severe growth retardation, severely pinched facies, high-pitched voices, and small male genitalia. Males have delayed puberty. Birth weight is normal, but birth length may be reduced. Motor development may be delayed and some are mildly retarded. Teething and fontanelle closure are delayed. Their hands and feet are small and, like pituitary dwarfs, they are obese and their body proportions are childlike.

**FIGURE 83-11** Schematic diagram of the GHR gene showing the sequence and location of point mutations. (From Phillips, J. A. III. *Molecular Biology of Growth Hormone Receptor Dysfunction*. Acta Paediatr. 1992, 363, 127–131.)

They may have spontaneous hypoglycemic episodes in infancy and usually have insulinopenia in response to glucose and arginine. ACTH, TSH, gonadotropin, and vasopressin secretion is normal. Fasting plasma GH concentrations are usually elevated, but may fluctuate from normal levels to over 100 ng/mL in the same patient. There is further elevation of plasma immunoreactive GH concentration following insulin-induced hypoglycemia and arginine infusion. Plasma IGF1 levels are low and, unlike those in GH-deficient patients, do not respond to GH administration. Furthermore, they are relatively unresponsive to the metabolic and growth-promoting effects of GH. It was first thought that this disorder was due to the synthesis of a structurally altered GH molecule which was immunologically active but biologically inert. Jacobs et al. used a receptor assay to show that the GHR is functionally defective, and Eshet et al. showed that GH

binding was absent in the livers of patients with Laron syndrome. The absence of both GHR activity and GHBP in Laron syndrome suggested that the GHR and GHBP might be identical or closely related. Further proof that Laron syndrome is due to GHR defects is the effectiveness of IGF1 in inducing GH-like metabolic responses in patients with the syndrome. Currently 61 GHR mutations are cataloged in the HGMD. Selected examples and their effect on GHR expression will be reviewed.

**83.2.4.14.3 GHR Deletions.** The first examples of GHR mutations reported were deletions of portions of the gene encoding the extracellular domain (Figure 83-11). Southern blotting showed altered restriction patterns of the GHR genes from patients with Laron syndrome who had no detectable GHBP and very low levels of IGF1. These and other studies using exon-specific probes were interpreted as showing deletions of exons 3, 5–6, and part of 4 from the GHR gene. How these two noncontiguous deletions arose remains unclear. Whereas 2/9 (22%) of patients studied by Godowski and associates had GHR deletions, Parks detected GH receptor deletions in 5/9 (56%) of the Laron syndrome probands studied (personal communication). The heights of patients with Laron syndrome ranged from –7 to –8.5 SD in those with GHR deletions and –5 to –9 SD in those with point mutations. Five families with GH insensitivity syndrome and partial deletions of the GHR gene have recently been reported in individuals with diverse ethnic backgrounds (99). A small (22 bp) deletion in GHR resulting in a frameshift and truncation of the GHR protein after amino acid 449 has been reported to result in loss of Stat5 signaling with a phenotype of Laron syndrome (100).

**83.2.4.14.4 GHR Point Mutations.** Multiple point mutations have been detected within the GHR gene (Figure 83-11). Amselem et al. detected a T to C substitution that converts the 96th residue of the extracellular domain from phenylalanine to serine. Duquesnoy et al. demonstrated that cells transfected with this mutant cDNA lacked GH binding activity. Interestingly, GH binding activity was found in the lysosomal fraction and the mutant proteins were located in the cytosol. These findings suggest that cells do not correctly transport the GHR with serine at position 96, and demonstrate the importance of phenylalanine at position 96, which is conserved in related cytokine receptors. Other missense mutations that affect protein trafficking and binding affinity as well as receptor expression and dimerization have been reported (101).

In a patient of northern European origin, a cysteine (TGC) to stop codon (TGA) mutation was detected at codon 38 in exon 4 (Figure 83-11). An arginine (CGA) to stop codon (TGA) mutation was found at codon 43 in exon 4 of two Mediterranean patients who were products of consanguineous marriages. Both stop codons truncate the GHR protein and delete most of its GHBP domain and all of its transmembrane and intracellular domains. These findings are consistent with the

**FIGURE 83-12** A woman with IGHD and her husband with Laron dwarfism.

lack of GHBP in each of the patients with Laron syndrome. The mechanism of the CGA to TGA mutation is consistent with deamination of 5-methylcytosine that preferentially occurs in CpG dinucleotides. Such dinucleotides often represent “hot-spots” for CG to TG or for CG to CA mutations, and 17 occur within the GHR gene (Figure 83-11). Two of these, at nucleotides 181 and 703, occur in CGA codons that could yield stop codons. An ATG to TTG mutation which abolishes the translation initiation codon and thus results in complete absence of GHR protein has also been reported (101). Up to 5–8% of patients with ISS may have GHR mutations.

**83.2.4.14.5 GHR Splicing Defects.** Rosenbloom et al. identified 20 patients with Laron dwarfism type 1 in an inbred population of Spanish extraction in southern Ecuador. These patients were –6.7 to –10 SD below the mean height and had limited elbow extension, blue sclerae, short limbs, hip degeneration, acrohypoplasia, and normal or superior intelligence. To determine the associated defect in the GHR gene, Berg et al. used denaturing gradient gel electrophoresis to analyze each exon of the GHR gene. Unusual fragments derived from exon 6 showed abnormal mobility, suggesting a 20- to 32-bp deletion. Genomic DNA sequencing showed an A to G substitution in the third position of codon 180, which is 24 nucleotides from the 3′ end of exon 6. Although this mutation does not cause an amino acid substitution, it produces a consensus 5′ or donor splice sequence within exon 6. Using allele-specific oligonucleotide probes, 45/46 Ecuadorian patients with Laron syndrome were found to be homozygous for this defect. This substitution produces a near-consensus donor splice site within exon 6 that results in the deletion of eight amino acids, owing to abnormal splicing of the 3′ end of exon 6. Deletion of these residues is thought to reduce the function of the GHR molecule. Interestingly, some individuals who are homozygous for this mutation apparently retain some GHR activity, suggesting that some normal splicing can occur. A point mutation in intron 9, which results in exon 9 skipping and creation of a stop codon in exon 10, has been reported. This splice defect results in a truncated protein which is missing most of the intracellular domain and causes GH resistance by a dominant-negative suppression of GHR signaling. Patients with this mutation also had elevated GHBP levels.

**83.2.4.14.6 GHRd3 Isoform.** The GHRd3 isoform results from genomic deletion of exon 3 and is polymorphic. GHRd3 appears to be sufficient for normal growth (102). In children with ISS and short stature due to SGA, the GHRd3 polymorphism has been associated with improved response to exogenous GH (103). Such data could eventually be used to individualize therapy.

**83.2.4.14.7 Clinical Relevance.** Significant genetic heterogeneity has already been demonstrated in GHR gene defects in Laron syndrome. Most of the differences seen in clinical severity may be due to this heterogeneity.

The height abnormalities of patients studied ranged from –5, –8, –10 SD in those homozygous for point mutations, deletions, and splicing abnormalities, respectively. Whether the clinical differences seen in blue sclerae, hip degeneration, and intelligence are due to the severity of the syndrome or to specific GHR alleles remains to be determined. From mutations found in familial GHD and beta thalassemia, it could be predicted that clinically milder and atypical cases of Laron syndrome will be found that have GHR abnormalities. Combinations of different mutations in single patients, referred to as genetic compounds, could be another source of variation in clinical severity. Indeed, a number of children with idiopathic short stature and low serum GHBP had heterozygous mutations in the GHR gene, resulting in partial resistance to GH. It has been estimated that GHR mutations account for up to 5% of all idiopathic short stature patients.

**83.2.4.15 Laron Dwarfism II (Post-Receptor Defects).** Lanes and colleagues described an adolescent male with proportionate dwarfism, a normal plasma GH response to stimulation and elevated IGF1 by bioassay, radioreceptor assay, and radioimmunoassay (OMIM 245590; Table 83-3). Bone age was clinically retarded, but by age of 15 his sexual development was well established; 24-h GH secretion was normal, as were his ACTH, TSH, and gonadotropin functions. In view of his elevated IGF1 and clinical hypopituitarism, peripheral unresponsiveness to IGF1 at either the receptor or the postreceptor level was postulated. Cultured fibroblasts from such a patient had a 50% decrease in IGF1 binding compared to controls. Patients with Laron dwarfism II have elevated serum GH, normal GHBP levels, and respond well to treatment with IGF1, indicating that their growth deficiency is due to a post-GHR defect (Figure 83-1). Woods et al. described a patient with severe growth failure, sensorineural deafness, and mental retardation who was found to be homozygous for a partial deletion of the IGF1 gene. RT-PCR analysis confirmed the deletion of exons 4–5, which would result in a severely truncated mature IGF1 peptide. Interestingly, this patient had only a slightly delayed bone age indicating that GH directly stimulates bone maturation.

After binding to the GH receptor, GH initiates signal transduction through a number of pathways, including the JAK-STAT pathway. Postreceptor defects in GH responsiveness have been described secondary to a STAT5b mutation (104,105).

IGF1 receptor (IGF1R) mutations have been described in patients with intrauterine growth retardation and poor postnatal growth (106). Patients with a deletion of the distal long arm of chromosome 15, where the IGF1R gene is located, have growth retardation, but a cause and effect relationship could not be established in vitro. It is likely that both IGF1R and postreceptor defects will be found in other children with combined intrauterine and postnatal growth retardation.

**83.2.4.16 African Pygmies.** Peripheral unresponsiveness to GH administration in the presence of normal concentrations of immunoreactive plasma GH and normal bioassayable IGF1 activity has been documented in the African Pygmies. This population, who inhabit the rain forests of equatorial Africa, resemble pituitary dwarfs in size and skeletal proportions, but do not have the truncal obesity, peculiar facies, and wrinkled skin of pituitary dwarfism. Following insulin-induced hypoglycemia and arginine infusion, plasma GH levels are normal but, like type I IGHD, they are insulinopenic and hypersensitive to the effects of exogenous insulin. They are completely unresponsive to the lipolytic, insulinotropic, and nitrogen-retaining properties of GH. Deficiency of IGF1 with normal IGF2 has been noted in these pygmies. Decreased serum GHBP and IGF1 levels were found to be significantly decreased in two Pygmy populations in the Philippines (107) and decreased IGF1 was described in the Central African Republic pygmies. Normal levels of serum IGF1 and 2, IGFBP3, GHBP, and GH in the African pygmies, compared to a neighboring population of normal size, have been reported by Geffner et al. Using HTLV-II transformed-lymphoblast cell lines from Efe pygmies, they demonstrated complete resistance to the growth-promoting actions of IGF1 and GH but normal stimulation by insulin, suggesting that non-responsiveness to IGF1 may be the cause of the short stature. In addition, no difference in the distribution of IGF1 alleles could be detected between pygmies and non-pygmy black Africans. Thus, it is not yet clear as to whether the GH unresponsiveness in the pygmies is secondary to a deficiency of IGF1 or to an IGF1 receptor or postreceptor defect.

## 83.2.5 Disorders of the Gonadotropin Pathway

**83.2.5.1 Hypogonadotropic Hypogonadism.** Kallmann syndrome (KS) (OMIM 308700) is a syndrome of hypogonadotropic hypogonadism coupled with anosmia, caused by failure of migration of GNRH neurons from the developing olfactory lobe to the hypothalamus. X-linked, autosomal dominant, and autosomal recessive forms are recognized (Table 83-1). The X-linked form is the most common and is caused by mutations in KAL1 (308700) which encodes anosmin-1, a extracellular matrix protein which acts as a chemoattractant for migrating neurons (108,109). Anosmin-1 also interacts with fibroblast growth factor signaling, and *FGFR1* (fibroblast growth factor receptor 1, OMIM 136350) has been shown to be the causative gene in autosomal dominant KS (OMIM 147950) (110). Multiple other genes have now also been implicated (Table 83-1). Interestingly, one of these genes, *CHD7*, has also been implicated in idiopathic hypogonadotropic hypogonadism as well as in CHARGE association (see above). Kim et al. analyzed the *CHD7* gene in 50 patients with KS (defined as HH

with anosmia or hyposmia) and 51 with IHH. They found mutations in three patients with KS and four with IHH. Interestingly, the same mutation (IVS8+5G>A) was found in one KS patient and one IHH patient, and this mutation has previously been reported in a patient with CHARGE syndrome. The authors propose that KS/IHH may represent a mild variant of CHARGE syndrome, with phenotypic expression modified by additional genes or epigenetic factors (111).

**83.2.5.2 Central Precocious Puberty.** Onset of puberty is complex process, in which onset of pulsative hypothalamic GNRH secretion is a key step. One regulator of this process is signaling of kisspeptin through its receptor (KISS1R, OMIM 604161; also called GPR54). Teles et al. have reported a case of central precocious puberty caused by an activating mutation of KISS1R (inactivating mutations may cause IHH, see above and Table 83-1) (112).

## 83.2.6 Disorders of Pituitary Hypersecretion and/or Neoplasia

Genetic disorders of pituitary hyperfunction are far less common than those of pituitary insufficiency (see Tables 83-1 and 83-5). At least four distinct syndromes have been recognized: multiple endocrine neoplasia, type 1 (MEN1), and type 4 (MEN4); Carney complex (CNC); and familial isolated pituitary adenoma (FIPA) (113). The most common form of hereditary pituitary neoplasia is MEN1; but most of these adenomas are PRL-secreting or nonfunctioning and only about 10% are GH secreting (somatotropinomas). In both CNC and IFS, the tumors are always somatotropinomas. Although multiple cases of familial acromegaly and of the amenorrhea-galactorrhea syndrome have been described in certain kindreds with no evidence of other endocrine involvement, these disorders may well represent limited forms of MEN1.

**83.2.6.1 Familial Isolated Pituitary Adenoma.** Although the majority of cases of acromegaly are sporadic, many families have been reported in which multiple members are said to be affected. Familial cases of prolactinoma have also been described. Initially, it was thought that familial cases involved only one type of tumor (usually GH secreting); however, it is now recognized that affected families may manifest many different types of tumors (114). Prolactinomas are most common, followed by somatotropinoma, followed by nonfunctioning tumors. Cushing's disease and thyrotropinomas occur but are very rare. Kindreds have been described in which all affected family members have the same type of tumor, while other kindreds have multiple different types. Genetic anticipation occurs with tumors appearing earlier in succeeding generations (114).

Approximately 15% of kindreds with FIPA have mutations in the aryl hydrocarbon receptor interacting protein gene (AIP, OMIM 605555) (115). AIP mutations

were first described by Vierimaa et al., in two kindreds with familial somatotropinomas (116). AIP appears to function as a tumor suppressor gene in pituitary tissues and it appears that a second hit in pituitary tissue is needed for an adenoma to occur, which would explain the relatively low penetrance in families with AIP mutations (115).

In an interesting historical corollary, Chahal et al. were able to extract DNA from teeth of the “Irish Giant,” a famous patient with gigantism who died in 1783 and whose skeleton was preserved in the Hunterian Museum in London, UK. They were able to demonstrate that the patient had a 910C-T mutation in his AIP gene. They used microsatellite studies to demonstrate that four contemporary kindreds in Ireland with FIPA and the same AIP mutation share a common ancestry with the Irish Giant and likely share the mutation through the founder effect (117).

Although AIP mutations explain a significant percentage of FIPA, a majority of cases do not have those mutations. There are at least nine other loci which show linkage to FIPA in affected kindreds without AIP mutations (118).

**83.2.6.2 Multiple Endocrine Neoplasia Type 1.** MEN1 (OMIM 131100) is a familial disorder characterized by multiple tumors or hyperplasia of the endocrine glands, most commonly parathyroid, pancreas, and pituitary (see also Chapter 85). The clinical manifestations of pituitary disease are dependent on the type of tumor; prolactinomas are most common with nonfunctioning and GH-secreting adenomas following. In any patient with a pituitary neoplasm, an effort should be made to rule out the involvement of the other endocrine organs, in both the patient and their close relatives.

The MEN1 syndrome is inherited as an autosomal dominant trait, with marked intrafamilial variable expressivity. The MEN1 gene (OMIM 613733) encodes a nuclear protein, menin, and a large number of inactivating mutations have been recognized. Currently, 333 mutations in the MEN1 gene are cataloged in the HGMD.

**83.2.6.3 Multiple Endocrine Neoplasia Type 4 (MEN4).** Multiple endocrine neoplasia type 4 (MEN4) (OMIM 610755) is a neoplastic syndrome similar to MEN1. It is also autosomal dominant, but clinical features vary somewhat, consisting primarily of pituitary tumors and hyperparathyroidism (119). Pellegata et al. identified mutations in the cyclin-dependent kinase inhibitor p27 (CDKN1B, OMIM 600778), another tumor suppressor gene (119).

**83.2.6.4 Carney Complex.** Carney et al. described a syndrome consisting of mucocutaneous and cardiac myxomas, spotty skin pigmentation, schwannomas, and endocrine overactivity. Pituitary gland adenomas occur in >20% of patients and are always GH secreting (120). The syndrome has been linked to two separate loci, 17q and 2p. The 17q gene associated with CNC encodes the

protein kinase A regulatory subunit 1 (PRKAR1A), inactivation of which leads to enhanced activity of the GH-releasing hormone-induced signal transduction pathway (121,122). This pathway exerts proliferative effects on somatotropes and is identical to that activated by somatic mutations in the Gs alpha gene, which has been associated with up to 40% of (nonfamilial) somatotropinomas and the developmental mutations occurring as a mosaic in patients with McCune–Albright syndrome, in which somatotrope hyperplasia and adenoma formation frequently occur. There are at least 32 mutations in PRKAR1A cataloged in the HGMD. CNC type II refers to those patients with linkage to chromosome 2p, in which the molecular defect is still not known.

### 83.3 POSTERIOR PITUITARY: GENETIC DISORDERS OF AVP DEFICIENCY

The posterior pituitary gland (neurohypophysis), which is derived from an invagination of the hypothalamus, is embryologically and functionally distinct from the anterior pituitary. The primary function of the neurohypophysis is the storage and secretion of the hormones arginine vasopressin (AVP, OMIM 192340) and oxytocin (OXT, OMIM 167050), which are synthesized by neurons in the supraoptic and paraventricular nuclei of the hypothalamus. Both hormones are synthesized and processed in the neuronal cell body and then transported down the neuronal axons (supraopticoneurohypophyseal tracts) to the posterior pituitary in SVs. The hormones are stored in the posterior pituitary and released into the circulation following appropriate stimuli; for AVP this includes hyperosmolarity and hypovolemia (123).

AVP is encoded by the AVP gene (OMIM 192340) on chromosome 20 as a prohormone. This protein includes the AVP moiety (encoding nine amino acids), a signal peptide, neurophysin II, and copeptin (Figure 83-13). The signal peptide guides the prohormone to the ER, where folding occurs. The prohormone then exits the ER to the Golgi apparatus where packaging into SVs occurs. Conversion to the active hormone AVP takes place in the SVs (123).

NDI is a syndrome characterized by polyuria, polydipsia, and dehydration secondary to a deficiency of AVP. This syndrome is characterized by acute thirst, especially for cold water, enormous daily urinary output (3–15 L/day), and persistent nocturia. If water is withheld, the patient rapidly loses weight and develops hypernatremic dehydration. It is distinguished from diabetes mellitus by the presence of dilute urine without glycosuria. A variety of acquired lesions of the hypothalamus, such as neoplasia, basilar skull fractures, granulomatous diseases, vascular lesions, meningitis, and encephalitis, can result in AVP deficiency. In ~50% of NDI cases, however, no obvious primary lesion can be found. It is quite likely that many of these idiopathic cases represent sporadic cases of the genetic form of the disease. Hereditary forms account for fewer than 10% of all cases of DI; of the

**FIGURE 83-13** Schematic representation of the AVP or AVP-neurophysin II gene. The AVP gene encodes the following: (1) a prepropeptide precursor that includes a signal peptide (SP) whose initiation codon (ATG) is shown; (2) the nonapeptide AVP; (3) the AVP carrier protein neurophysin II (NPII); and (4) a glycoprotein copeptin (CP) whose function is unknown.

hereditary forms, nephrogenic DI is actually more common. We will focus on NDI here.

### 83.3.1 Autosomal Dominant Neurohypophyseal Diabetes Insipidus

In 1841, Lacombe first documented a familial form of DI; he described excessive thirst and polyuria in five males and three females in two generations of a family. Numerous other families with multiple affected members have since been described. The signs and symptoms of this autosomal dominant disorder are quite similar to those of the acquired forms of DI. There is, however, a great deal of intrafamilial variability in the clinical severity and age of onset of the disease. In one large family, urinary output varied from 3–4 to 15–20 quarts per day among affected relatives. Some, but not all, affected individuals have an increase in fluid requirements during febrile episodes, exercise, or pregnancy. In most cases, the onset of the disease occurs in infancy, but symptoms may not occur until late childhood or adolescence. Symptoms may abate in old age. In many of the affected families, the condition is regarded as an unpleasant family habit, rather than a disease. Apart from drinking enormous quantities of water, the disease does not impair health or well-being, unless free access to water is denied. Typical imaging studies of the brain show absence of the pituitary bright spot on MRI; however, the bright spot may still be present in young children.

Plasma levels of AVP are very low or undetectable in these cases. AVP secretion may be normal for the first few years of life, but then decreases rapidly. Autopsy studies of individuals with autosomal dominant NDI (ADNDI) or sporadic idiopathic forms of the disease have found a severe reduction in the number of neurosecretory neurons in both supraoptic and paraventricular nuclei of the hypothalamus. There is associated gliosis, and in the paraventricular nucleus the small- to medium-sized neurons may be normal or reduced in number. The posterior pituitary gland has been found to be normal in size or small in these cases, but no neurosecretory material was observed on special staining. Although these individuals appear to have no neurosecretory neurons

in their hypothalamic nuclei and have all the signs and symptoms of AVP deficiency, OT secretion appears to be normal in most. Several females with ADNDI, including one in whom a marked deficiency of neurosecretory cells was documented, have undergone normal pregnancies and deliveries and have successfully nursed their children. Thus, they appear to secrete OT, despite the deficiency of neurosecretory neurons. Several patients with DI have been reported, however, who have had difficulty in expelling the fetus and placenta during labor and/or inability to secrete milk, suggesting that OT deficiency might also exist. In one such family, plasma levels of OT and its carrier protein were normal, but did not increase normally following estrogen administration.

**83.3.1.1 Animal Models of ADNDI.** Neurohypophyseal DI is an autosomal recessive trait in the Brattleboro rat. Although these animals have an absolute deficiency of AVP in their hypothalamus and posterior pituitary, unlike in the human disease the rats have hypertrophy of the hypothalamus and pituitary system. The neurons in the supraoptic nucleus are extremely well developed but lack neurosecretory granules. Similar, but less marked, changes are seen in the paraventricular nuclei, and the posterior lobe of the pituitary is three to four times heavier than normal. Heterozygous animals have a reduced concentration of AVP in the hypothalamus and pituitary and have deficient secretion and release of the hormone. In vivo, ADH and its neurophysin carrier are absent, but markedly reduced levels of ADH mRNA are present in the hypothalamus. The molecular defect in the Brattleboro rat has now been found to be a single deletion of a G residue in the segment of the AVP gene which encodes for the neurophysin carrier protein. The basic defect in the autosomal recessive variety of DI in the rat is decreased synthesis of active hormone with compensatory hypertrophy of the secretory neurons. The differences in the genetics and pathogenesis of DI between humans and rats support the general rule of recessive inheritance of peptide hormone deficiency syndromes.

Russell and colleagues established murine knock-in models of two different naturally occurring human mutations that cause ADNDI (124). A mutation in the signal peptide of AVP, ala-1 thr (A-1T; OMIM 192340.0003), is associated with a relatively mild phenotype or delayed presentation in humans. This mutation caused no apparent phenotype in mice. In contrast, heterozygous mice expressing a mutation that truncates the AVP precursor, Cys98Stop (C98X; also C67X in alternate numbering system; OMIM 192340.0005), exhibited polyuria and polydipsia by 2 months of age; these features of DI progressively worsened with age. Studies of the paraventricular and supraoptic nuclei revealed induction of the chaperone protein BiP (OMIM 138120) and progressive loss of AVP-producing neurons relative to oxytocin-producing neurons. In addition, AVP gene products were not detected in the neuronal projections, suggesting retention of wild-type and mutant AVP precursors

**FIGURE 83-14** (A) Pedigree of ADNDI family obtained from affected family members, showing affected individuals as solid squares (males) and solid circles (females). Symbols filled with a question mark indicate subjects not formally tested or whose phenotype is uncertain. (B) DNA sequence analysis of DNAs from a mother and her three children all of whom have autosomal dominant neurohypophyseal DI (see pedigree above). Note the G to A transition at codon 19 of the signal peptide, which corresponds to –1 of AVP and encodes a GCG (Ala) to ACG (Thr) substitution.

within the cell bodies. This murine model recapitulated many features of the human disorder and demonstrated that expression of the mutant AVP precursor leads to progressive neuronal cell loss, presumably through a dominant-negative effect (see below).

**83.3.1.2 Molecular Pathophysiology of ADNDI.** A major function of ADH is to promote resorption of water by the kidney when plasma osmolality increases. Once secreted, AVP travels through the circulation to the kidney, where it binds to AVP receptor 2 (AVPR2). Through a cAMP mediated signal cascade, this binding causes aquaporin 2 (AQP2) to be translocated to the luminal membrane of the renal tubular cell, resulting in resorption of water. Defects in both of these genes have been described, resulting respectively in X-linked nephrogenic DI or autosomal dominant nephrogenic DI (OMIM 304800, 125800). Mutations causing ADNDI may affect the signal peptide, AVP, or neurophysin II regions of the gene. A majority of mutations lead to ADNDI by affecting protein folding and transport in the ER. For example, mutations in the signal peptide region may affect signal peptide cleavage and mutations in neurophysin II affect protein folding. Mutations in the AVP region of the gene may cause either folding problems (resulting in a dominant phenotype) or receptor binding defects (resulting in a recessive phenotype, see following). For example, a G to A transition which changes the last codon of the signal peptide portion of the AVP gene affects signal peptide cleavage and causes NDNDI (Figure 83-14). At least 60 mutations in the AVP gene have been reported, of which a majority occur in exon 2 which encodes neurophysin 2 (123). In vitro studies demonstrate that abnormally folded precursors are retained in the ER, and long-term cell culture studies and animal models suggest that this accumulation leads to cytotoxic effects which ultimately results in degeneration of the affected neurons (124–126). This at least partially explains the delayed onset of ADNDI in most kindreds, a similar mechanism to other dominant-negative disorders such as IGHD Type 2 (discussed earlier in this chapter). However, in a mouse model similar to that used by Russell et al., Arima et al. found that polyuria progressed

**TABLE 83-6 Summary of AVP Mutations Causing Neurohypophyseal Diabetes Insipidus<sup>a</sup>**

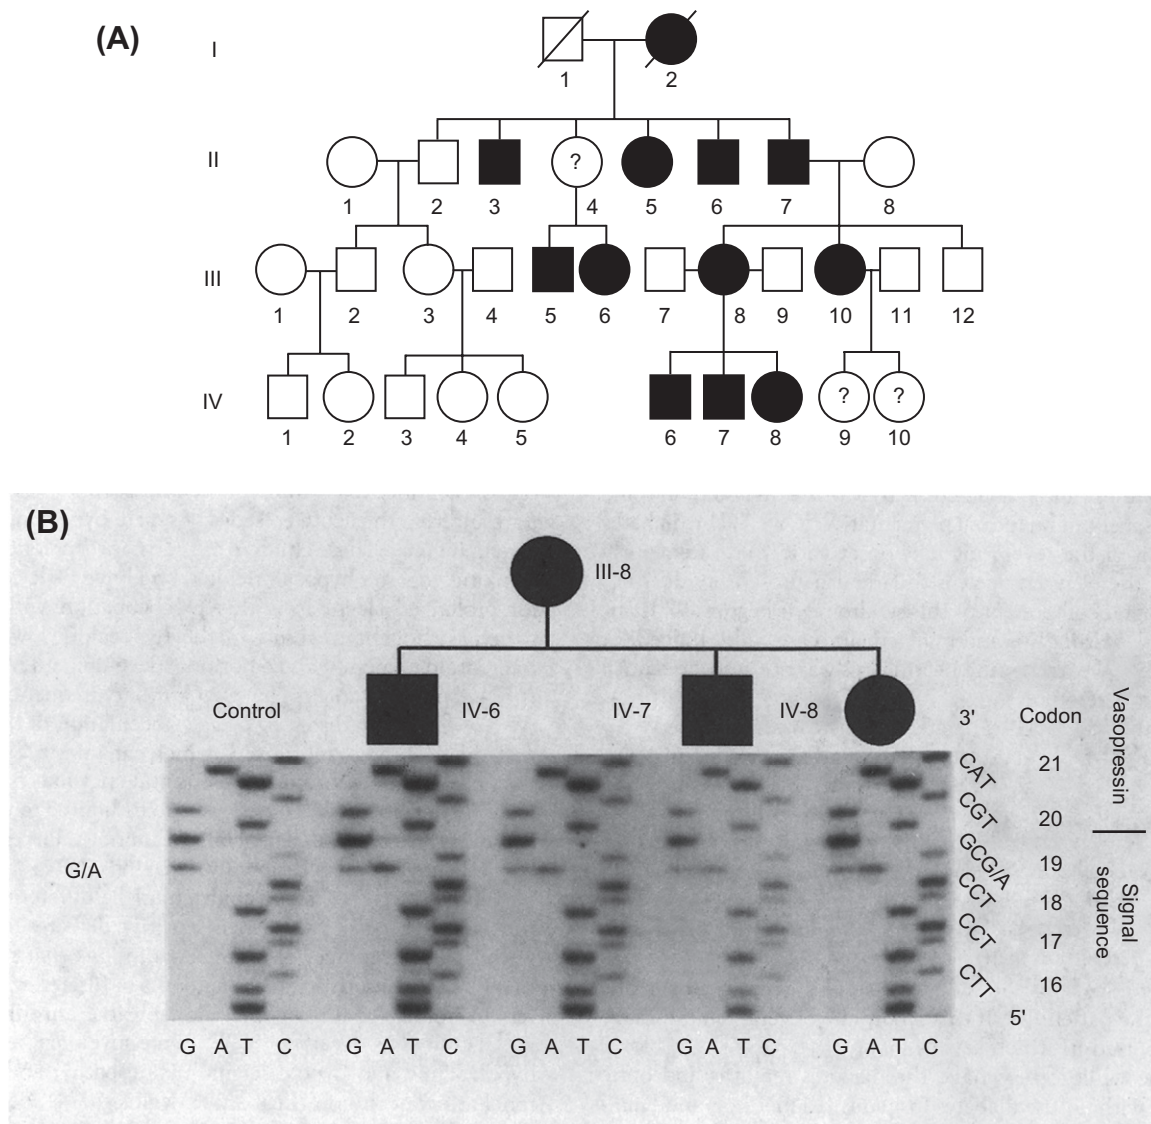

Mutation Type	Number of Mutations
Missense/nonsense	53
Splicing	0
Regulatory	0
Small deletions	5
Small insertions/deletions	2
Complex rearrangements	0
Total	60

**FIGURE 83-15** In the pathogenesis of FNDI, normal and Cys67Ter AVP products interact to prevent AVP secretion. These products also accumulate within, damage, and cause loss of AVP secretory cells. (From Phillips, J. A. III. Dominant-negative diabetes insipidus and other endocrinopathies. *J. Clin. Invest.* **2003**, 112, 1641–1643.)

even before neuronal loss occurred, suggesting that cellular dysfunction due to accumulation of abnormal proteins in the ER may also be a cause of progressive ADNDI (124,127). The cause of variation in age of onset between and within kindreds remains to be discovered; however, it is plausible that it could be at least partially explained by variations in modifying genes (such as those regulating ER protein quality control) and/or by epigenetic phenomena. See Figure 83-15 for an explanation of the dominant negative-mechanism of central DI due to AVP gene mutations, and Table 83-6 for a summary of known mutations. See Figure 83-16 for a comparison of the general mechanisms of autosomal recessive, autosomal dominant, and dominant-negative genetic disorders. Phillips tabulated 21 disorders caused by mutations in
